ACKNOWLEDGMENTS

First and foremost, I would like to thank my advisor, Dr. Jianxin Ma, for giving me the opportunity to obtain my doctoral training in his lab. The Ma Lab is an excellent platform for both study and research, with experts in different areas, and I have learned a lot from everyone. From Dr. Ma in particular, I have learned how to think through questions critically, solve problems in a timely manner, and present my results more efficiently. I will definitely benefit from these problem-solving and presentation skills throughout my life.

My special thanks also go to my advisory committee members, Dr. Mitchell R. Tuinstra, Dr. Steven R. Scofield, Dr. Tesfaye Mengiste, Dr. Rajat Aggarwal as well as former committee member Dr. Oswald Crasta, for their generosity in serving on my committee and their insightful suggestions and valuable feedback throughout my course and research.

I also would like to thank all of my lab mates, Dr. Lianjun Sun, Dr. Dajian Zhang, Dr. Zhenyan Miao, Dr. Bo Ren, Dr. Xutong Wang, Dr. Jingbo Duan, Liyang Chen, Chance Clark, Gabriel Fear, for their tremendous assistance in the past six years, and thank Tomara Fleury and Dr. Guohong Cai for their help in resistance screening. I also would like to thank Jim Beaty and his team for the help in field work at ACRE.

I would like to thank Corteva Agriscience™ (Dow AgroSciences) for funding this project, and thank Jon Massman and John Woodward, for their leadership in the Purdue University-Corteva Agriscience project collaboration, thank Kevin Fengler, Joy Bolar, Victor Llaca, Jon Myrvold, David Oneal, Daleen van Dyk, Ashley Hudson, Jesse Munkvold, Andy Baumgarten, Jeff Thompson, Ajit Nott, Lyudmila Sidorenko, Abhijit Sanyal, Jon Allen and Tyler Engelhart, for their technical support in genotyping, transformation, sequence analysis, resistance screening and greenhouse coordination.

Last but not least, I would especially like to thank my family. My parents and brother deserve special thanks for their continued support and encouragement. My wife, Fan Zuo, has been

extremely supportive of me since we got married. My daughter, Yimi Wang, and my upcoming son have brought me endless happiness.

ABSTRACT

Phytophthora root and stem rot is the most destructive soybean soil-borne disease worldwide and can be managed using soybean cultivars with genes conferring resistance to *Phytophthora sojae*. Here we show that soybean *Rps11* is an ~27-kb nucleotide-binding site leucine-rich repeat (NLR) gene that confers broad-spectrum resistance to the pathogen. This giant gene is located in a genomic region containing 12 unusually large NLR genes of a single origin and was formed by rounds of intergenic/intragenic unequal recombination that involves the promoter regions and the LRR regions. Comparison of the genomic region in the *Rps11* donor line with its corresponding regions in 29 diverse soybean genomes revealed drastic regional diversification including NLR copy number variation ranging from 5 to 23, and absence of allelic copy of *Rps11* in all 29 genomes. This study highlights innovative evolution and complexity of an NLR cluster and enables precise selection of *Rps11* for cultivar improvement.

CHAPTER 1. INTRODUCTION

Soybean (*Glycine max*) is the most important legume crop, providing 69% of world protein meal and 28% of vegetable oil (www.soystats.com). However, Phytophthora root and stem rot (PRSR), caused by the soil-borne pathogen *Phytophthora sojae*, threatens global soybean production, with annual losses of \$200 million in the United States and 1-2 billion worldwide (Dorrance et al., 2007; Tyler, 2007). Deployment of soybean varieties with genes conferring durable and broad-spectrum resistance is the most effective and environmentally friendly strategy to prevent PRSR (Dorrance and Schmitthenner, 2000; Hartman et al., 1999). *Rps1-k* has been widely used in commercial cultivars since 1982 because of its excellent resistance to known races of *P. sojae* (Gordon et al., 2006). However, an increasing number of isolates of *P. sojae*, such as Race 25 and Race 31, have been reported in subsequent years to be virulent to *Rps1-k* (Abney et al., 1997). Studies suggested that *P. sojae* populations could shift rapidly under strong selection pressure (Kaitany et al., 2001; Tooley and Grau, 1982), and individual Rps genes could remain effective for only 8 to 15 years of deployment in cultivars (Schmitthenner, 1985). Therefore, it is highly desired to identify novel Rps genes with durable and broad-spectrum resistance to *P. sojae* for effective management of PRSR.

To this end, more than 30 loci/alleles resistant to *P. sojae* (Rps) have been identified in past decades, most of which were mapped to genomic regions enriched in nucleotide-binding site leucine-rich repeat (NLR) genes (www.soybase.org). Unfortunately, the complex genomic variations found at these loci, including structural and copy number variations, have hindered understanding of the molecular mechanisms underlying the resistance and restricted their application in soybean breeding. First, the high sequence similarity among the different NLR genes often makes it difficult to find unique markers tightly linked to the resistant gene within an NLR gene cluster. Second, marker-assisted introgression is not only time-consuming but also leads to the introduction of an entire cluster of NLR genes, putting the resistant gene at high risk of being disrupted by unequal recombination between different NLR genes. Therefore, precise isolation of the resistant gene from NLR gene clusters is highly desirable, as it will allow more accurate, efficient, and stable introduction of resistance genes into target soybean cultivars.

CHAPTER 2. LITERATURE REVIEW

2.1 Plant defense strategies and known Rps loci

Plant defense includes both constitutive and induced strategies to protect plant from pathogen invasion (Anderson et al., 2010; Doughari, 2015). Constitutive defense includes physical barriers that can avoid the pathogens from entering and spreading in the plant cell and tissues, and biochemical reactions with products that can inhibit or kill the pathogens (Osbourn, 1996; Underwood, 2012). Induced defense also consists of two layers of protection. The first layer is known as pathogen associated molecular pattern (PAMP) triggered immunity (PTI) that recognizes conserved molecules or structure of pathogens and is usually not race specific; The second layer is effector triggered immunity (ETI) that recognizes the effectors released by pathogens and is usually race specific (Jones and Dangl, 2006). Soybean defense against *Phytophthora sojae* is usually ETI controlled by Resistant-to-*P.sojae* (Rps) genes.

For effective management of PRSR, about 34 Rps loci/alleles have been identified onto nine soybean chromosomes in past decades (Table 2.1). Among these loci/alleles, *Rps1a*, *Rps1b*, *Rps1c*, *Rps1d*, *Rps1k*, *Rps7*, *Rps9*, *RpsYu25*, *RpsZheng*, *RpsYD29*, *RpsX*, *RpsHC18*, *RpsQ*, *RpsHN*, *RpsUN1*, *RpsWY* and *RpsGZ* were mapped in a genome region on chromosome 3, forming the largest cluster of Rps loci (Table 2.1). The second largest cluster of Rps loci is located on chromosome 18, including *Rps4*, *Rps5*, *Rps6*, *Rps12* and *RpsJS* (Table 2.1). Chromosome 13 has the third largest cluster of Rps loci, harboring *Rps3a*, *Rps3b*, *Rps3c* and *RpsSN10* (Table 2.1). Besides these Rps cluster, *Rps2* and *RpsUN2* are located on chromosome 16; *RpsZS18* is located on chromosome 2; *Rps11* is located on chromosome 7; *Rps8* is located on chromosome 8; *RpsSu* is located on chromosome 10; *Rps10* is located on chromosome 17; *RpsYB30* is located on chromosome 19 (Table 2.1). Interestingly, most of these Rps loci/alleles were mapped into genome regions enriched with NLR genes. Since these loci are identified from various donor lines, whether they are controlled by different alleles of the same NLR gene or different NLR genes remain unclear.

2.2 Summary of released high-quality soybean genomes

Soybean (*Glycine max*) is proposed to be domesticated from its wild relative, *Glycine soja*, ~6,000-9,000 years ago (Carter et al., 2004; Kim et al., 2012). Two rounds of whole genome duplication have occurred at approximately 59 and 13 million years ago, respectively, resulting in a highly duplicated genome with nearly 3/4 of the genes present in multiple copies (Schmutz et al., 2010). In 2010, Schmutz *et al.* reported the first chromosome-level reference genome of a soybean cultivar, Williams 82 (Schmutz *et al.*, 2010). However, a lot of sequencing gaps are still present in this reference genome, especially in genome regions enriched of nucleotide-binding leucine-rich repeat genes (NLR), due to the limitation in sequencing technology.

In 2018, Shen *et al.* reported the first high-quality soybean reference genome, Zhonghuang 13, assembled based on a combination of SMRT, Hi-C and optical mapping data (Shen et al., 2018) and most of the NLR gene clusters were well assembled (Table 2.2). In 2019, Xie et al. reported the first high-quality reference-grade genome of wild soybean (Table 2.2), W05, and a few structural variations has been identified compared to *G. max* genomes (Xie et al., 2019). Another milestone of soybean genome sequencing is the pan-genome of wild and cultivated soybeans, release by Liu *et al.* in 2020. The authors reported the high-quality genomes of 26 soybean accessions, including 3 wild soybeans, 9 landraces and 14 elite cultivars, which are selected as representatives of 2,898 accessions (Table 2.2). The breakthrough sequencing and assembly technologies have allowed us to decode complete complex NLR gene regions that are highly repetitive and variable in gene copy number and structure. For example, the physical distance of the NLR gene cluster in the *Rps11* region ranges from 422 kb in SoyW02 to 1,206 kb in SoyC10 (Table 2.2), suggesting complicate structural and copy number variations. Besides the 29 released soybean genomes, ~ 4,000 soybean accessions have been re-sequenced and several million single nucleotide polymorphisms (SNPs) and insertions/deletions (InDels) have been identified (Liu et al., 2020; Valliyodan et al., 2021; Zhou et al., 2015), and over 20,000 soybean germplasm have been genotyped using the Illumina Infinium SoySNP6k BeadChip (Illumina, San Diego, Calif. USA) (Song et al., 2015), which have highly accelerated the genetic study and breeding of soybeans.

2.3 *Phytophthora sojae* and virulence genes

Phytophthora is a genus of plant-damaging oomycetes with more than 170 identified species (Goheen and Frankel, 2009), many of which are plant pathogens of considerable economic importance such as *Phytophthora infestans* that caused the Irish potato famine and subsequent

diaspora (Nowicki et al., 2012), and *Phytophthora sojae* that causes the Phytophthora stem and root Rot (PRSR) of soybean, which has been ranked as the second most destructive soybean disease since it was first found in Indiana in 1948 (Kaufmann and Gerdemann, 1958; Wrather and Koenning, 2009). The zoospores produced by *P. sojae* can be attracted by soybean roots in wet conditions, and then infect plant tissues. Infected soybean plants usually develop lesions on root and stem and the entire plants are eventually killed.

P. sojae is a diploid organism with a genome size ~95 Mb (Tyler et al., 2006) and the pathogenic mechanisms of *P. sojae* have been extensively explored. Several hundreds of effector proteins have been identified to date. Among these effector proteins, a conserved RXLR motif has been proposed to play crucial role in virulence by *P. sojae* (Dou et al., 2008; Jiang et al., 2008). In addition, several dozen of *P. sojae* isolates have been re-sequenced, which will benefit the studies of the natural diversity of *P. sojae* populations and guide better deployment of Rps genes towards effective management of PRSR.

CHAPTER 3. MATERIALS AND METHODS

3.1 Plant materials

The mapping populations were generated from an initial cross between PI 594527 and Williams. In 2015, 2640 F3 plants derived from heterozygous F2 individuals were screened for identification of recombinants. In 2016 and 2017, two additional larger populations, including 7680 and 6730 F4 plants respectively, derived from heterozygous F3 individuals, were screened for more recombinants (Figure 3.1). Only the recombinants with one side heterozygous and the other side homozygous Williams genotype were used for fine mapping, because the two expected phenotypes could be easily and accurately distinguished.

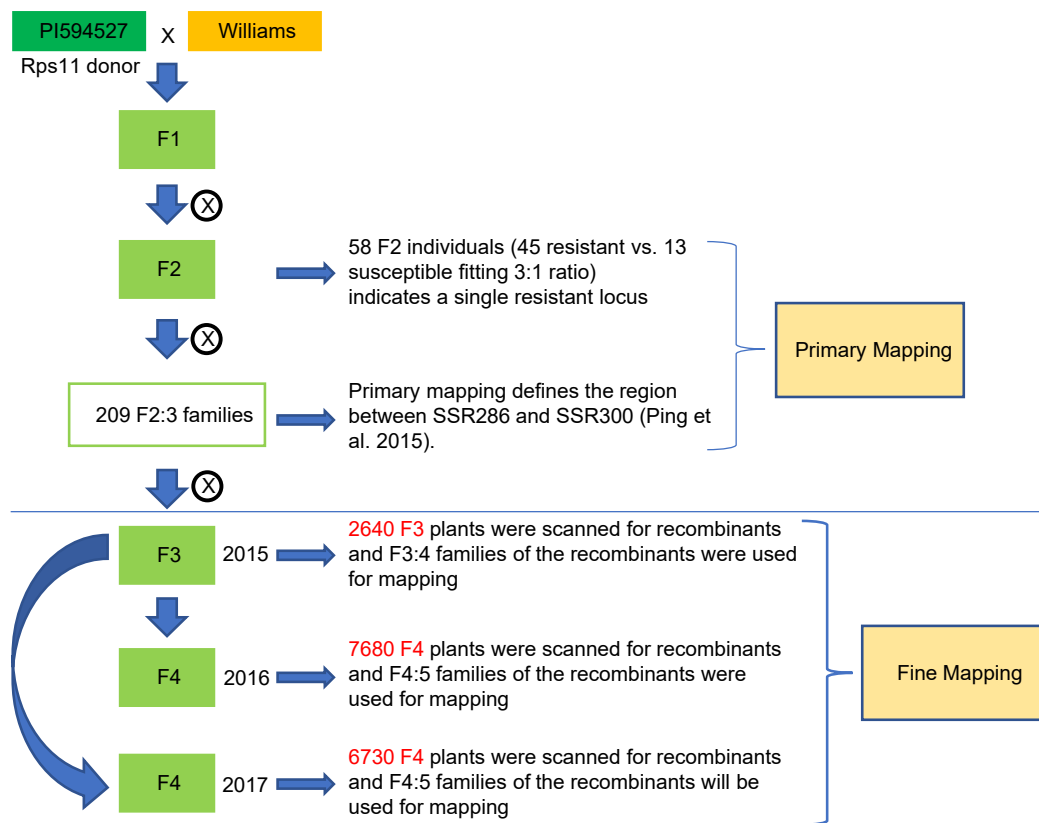

Figure 3.1 Flowchart of the *Rps11* fine mapping process and the plant materials used.

3.2 Isolates of *P. sojae* and resistance evaluation

Fourteen isolates of *P. sojae* (Table 3.1) were used for inoculation of a progeny populations, including 14 lines with *Rps11/Rps11* (PI 594527) genotype and 14 lines with *rps11/rps11* (Williams) genotype derived from the mapping population; 158 isolates collected from fields across Indiana (Figure 3.2 and Table 3.2) were used to further explore the resistance spectrum of the *Rps11* locus. Race 1 was used for the inoculation of all the recombinants.

For inoculating the recombinants, about 30 seedlings from each line were inoculated with *P. sojae* Race 1 using a protocol previously described (Dorrance *et al.*, 2007; Lin *et al.*, 2013). Lines with less than 25% of progenies surviving after inoculation were classified as susceptible (S); lines with more than 25% of progenies surviving were classified as segregating (H). Evaluation was repeated twice for each line. For resistance spectrum tests, lines with less than 25% of progenies surviving after inoculation were classified as susceptible (S), lines with 25% to 75% of progenies surviving after inoculation were classified as partially resistant (H), and lines with more than 75% of progenies surviving after inoculation were classified as completely resistant (R).

3.3 Genotyping the recombinants.

SSR markers and insertion/deletion markers (InDel) were identified and designed based on re-sequencing data of the two parental lines. Marker_176kb was a dominant marker that could only be amplified from the donor line. Only the markers with a unique hit at the *Rps11* region were used for fine mapping. Kompetitive allele specific PCR (KASP) makers were also used to identify and genotype the recombinants from the 2017 mapping population. All markers used in this study are listed in Table 3.3.

3.4 Long and short read genome sequencing

Long-read data was generated using the Pacific BioSciences (Menlo Park, CA, USA) Sequel platform at Corteva Agriscience™ (Johnston, IA, USA). Eight SMRT cells were performed with 10-hr movies and v6 chemistry. Raw subreads were filtered to a minimum of 12 kb generating 77× genome coverage. The raw subread N50 length was 28.9 kb. Linked short-read data were generated by sequencing 10X Genomics (Pleasanton, California) Chromium libraries at Corteva Agriscience™ on the Illumina (San Diego, California) HiSeq2500 platform in a PE151 configuration. The coverage depth and mean molecule length for the Chromium library were 45.2× and 93.8 kb, respectively.

3.5 Genome assembly and sequence polishing

Canu (Koren et al., 2017) v1.8 (<https://github.com/marbl/canu>) was used to self-correct the raw subreads and to assemble the corrected reads into contigs. The following changes were made to the default parameters: `correctedErrorRate=0.065`, `corMhapSensitivity=normal`, and `ovlMerDistinct=0.99`. A minimum contig length of 30 kb was applied. Additional sequence polishing was performed by aligning raw PacBio subreads to the contig assembly using `pbbmm2` v0.12.0 (<https://github.com/PacificBiosciences/pbbmm2>) and applying the Arrow algorithm from the Genomic Consensus package v2.3.2 (<https://github.com/PacificBiosciences/GenomicConsensus>) to identify and correct remaining consensus errors in the contigs. These tools were acquired from `pbioconda` (<https://github.com/PacificBiosciences/pbioconda>). The consensus sequence accuracy was further enhanced by complementing the long read contig assembly with Chromium linked short-reads. Chromium datasets were aligned to contigs using Long Ranger v2.2.2. The sequence assembly polishing tool Pilon (Walker et al., 2014) v1.22 (<https://github.com/broadinstitute/pilon>) was used to correct individual base errors and small indels from the Chromium data aligned to the contigs using the “`--fix bases --minmq 30`” parameters.

3.6 Creating genome maps

Genome maps were generated in the Bionano Saphyr platform at Corteva Agriscience™ using the Direct Label and Stain (DLS) approach (Ou et al., 2020). Nuclear DNA was isolated from leaf

tissue using a modified version of the Bionano Prep™ Plant Tissue DNA Isolation protocol (<https://Bionanogenomics.com/wp-content/uploads/2017/01/30068-Bionano-Prep-Plant-Tissue-DNA-Isolation-Protocol.pdf>) that did not include a gradient centrifugation step. DLE-1–labeled molecule data were filtered to create a dataset with a molecule N50 of 441 kb and 267× coverage. This dataset was assembled via the Bionano Genomics Access software platform (Solve3.2.2_08222018) with the configuration file `optArguments_nonhaplotype_noES_noCut_DLE1_saphyr.xml`. The resulting genome maps were filtered to remove coverage and length outliers. The final genome map assembly consisted of 45 maps with a genome map N50 of 26.7 Mb and a total map length of 985 Mb.

3.7 Hybrid scaffolding of genome maps with sequence contigs.

Hybrid scaffolds were generated from the polished contigs and the Bionano genome maps using the Bionano Genomics Access software (Solve3.3_10252018) and the DLE-1 configuration file `hybridScaffold_DLE1_config.xml`. In addition to auto-conflict resolution performed by the software, manual curation was performed to resolve overlapping and embedded contigs by providing additional “Conflict resolutions” and re-running the hybrid scaffolding. In the final product, the assembly had 43 hybrid scaffolds (Scaffold N50= 26.4 Mb, Total scaffold length= 978.1 Mb) with 229 leftover contigs that were not scaffolded with a combined length of 21.3 Mb.

3.8 Building chromosome-scale pseudomolecules

A reference-based approach was feasible to create chromosome-scale pseudomolecules using the Glycine max Wm82.a2.v1 reference assembly (<https://phytozome.jgi.doe.gov/>), because only an average of 2.15 scaffolds per chromosome needing to be placed. To map hybrid scaffolds to the reference, each scaffold was chunked into 100-bp fragments and then aligned to the reference genome using minimap2 (Li, 2018) v2.10 (<https://github.com/lh3/minimap2>). Then, a custom script was used to determine the chromosome position and orientation for each scaffold based on the alignment of each “chunked scaffold cloud”. All scaffolds were able to be placed using this method. Leftover unscaffolded contigs were concatenated with 100-bp N-gaps and assigned to Chr00.

3.9 NLR gene annotation and expression analysis

NLR genes were annotated using NLR-Annotator (Steuernagel et al., 2020). RNA samples were extracted from mixed stem tissues from seedlings of each key recombinants using RNeasy Plant Mini Kit (Cat No. 74904, Qiagen) and were treated with RNase-Free DNase Set (Cat No. 79254, Qiagen) to remove DNA. RNA-seq was performed by Purdue Genomic Core Facility (<https://www.purdue.edu/hla/sites/genomics/>). RNA-seq data were mapped to the genome of the donor line using STAR (Dobin et al., 2013) and expression was calculated based on the number of reads mapped to each NLR gene.

3.10 Plasmid Construction and Transformation

To make the over-expression construct for the *Rps11* candidate gene R6, the CDS of R6 was synthesized by Genscript as 3 fragments and assembled with AtUbi3 promoter and Gateway ATT sites by homologous recombination in yeast to make a Gateway entry vector (Muller et al., 2012). This was recombined into a Gateway destination vector by LR reaction using Gateway Technology with Clonase II (25-0749, Invitrogen) for transformation into *Ochrobactrum*. *Ochrobactrum*-mediated soybean embryonic axis transformation was done as previously described (US20180216123A1; WO2020/005933A1; WO2020/092494A1). Mature dry seeds of soybean cultivar 93Y21 were disinfected using chlorine gas and imbibed on semi-solid medium containing 5g/l sucrose and 6 g/l agar at room temperature in the dark. After an overnight incubation, the seed was soaked in distilled water for an additional 3-4 hrs at room temperature in the dark. Intact embryonic axis explants were isolated and transferred to the deep plate with 15 mL of *Ochrobactrum haywardense* H1-8 suspension (OD 0.5 at 600 nm) in infection medium composed of 1/10X Gamborg B5 basal medium, 30 g/L sucrose, 20 mM MES, 0.25 mg/L GA3, 1.67 mg/L BAP, 200 μ M acetosyringone and 1 mM dithiothreitol in pH 5.4. The plates were sealed with parafilm (“Parafilm M” VWR Cat#52858), then sonicated (Sonicator-VWR model 50T) for 30 seconds. After sonication, embryonic axis explants were transferred to a single layer of autoclaved sterile filter paper (VWR#415/Catalog # 28320-020). The plates were sealed with Micropore tape (Catalog # 1530-0, 3M, St. Paul, MN)) and incubated under dim light (5-10 μ E/m²/s, cool white fluorescent lamps) for 16 hrs at 21°C for 3 days.

After co-cultivation, the base of each embryonic axis was embedded in shoot induction medium (R7100, PhytoTech Labs) containing 30 g/L sucrose, 6 g/L agar and 25 mg/L spectinomycin (S742, PhytoTech Labs) as a selectable agent and 500 mg/L cefotaxime (GoldBio, ST Louis, MO, USA) in pH5.7. Shoot induction was carried out at 26°C with a photoperiod of 18hrs and a light intensity of 40-70 $\mu\text{E}/\text{m}^2/\text{s}$. After 4-6 weeks in selection medium, the spectinomycin-resistant shoots were cut and transferred to $\frac{1}{2}$ strength MS rooting medium (M404, PhytoTech Labs) containing 15 g/L sucrose, agar 6 g/L, 10 mg/L spectinomycin and 250 mg/L cefotaxime for further shoot and root elongations.

Marker-free transgenic soybean plants were generated by the Cre-lox site-specific recombination system using heat shock treatment. For heat shock treatment of soybean, 2-4 cm T0 plantlets with roots in 100 x 25 mm Petri dishes on spectinomycin free-rooting medium were transferred into a Percival incubator (Percival Scientific, Perry, IA, USA) at 45°C, 70 % humidity for 2 hrs in the dark. After the heat shock treatment, T0 plantlets were transferred to moistened Berger BM2 soil (Berger, Saint-Modeste, QC, Canada), and kept enclosed in clear plastic tray boxes in a Percival incubator at 26°C with a 16 hr photoperiod at 250-350 $\mu\text{E}/\text{m}^2/\text{s}$. Leaf punch samples were collected for molecular analyses from newer growth 2 weeks after acclimatization of T0 events. Hardened plantlets were potted in 2-gallon pots containing moistened SunGro 702 and grown to maturity for harvest in a greenhouse. The presence of the construct in the transgenic plants was confirmed by PCR with primers specific to the cloning vector and expression analysis of R6 in the transgenic plants by qPCR.

3.11 Data access

All the Pacbio raw sequence data, the genome assembly, Illumina short-reads sequencing data and RNA-seq data from this article have been deposited in National Center for Biotechnology Information (NCBI, <https://www.ncbi.nlm.nih.gov/>) database under BioProject PRJNA718574.

3.12 Material availability

Novel biological materials described in this publication may be available to the academic community and other not-for-profit institutions solely for non-commercial research purposes upon

acceptance and signing of a material transfer agreement between the author's institution and the requestor. In some cases, such materials may originally contain genetic elements described in the manuscript that were obtained from a third party(s), and the authors may not be able to provide materials including third party genetic elements to the requestor because of certain third-party contractual restrictions placed on the author's institution. In such cases, the requester will be required to obtain such materials directly from the third party. The authors and authors' institution do not make any express or implied permission(s) to the requester to make, use, sell, offer for sale, or import third party proprietary materials. Obtaining any such permission(s) will be the sole responsibility of the requestor. In order to protect Corteva Agriscience™ proprietary germplasm, such germplasm will not be made available except at the discretion of Corteva Agriscience™ and then only in accordance with all applicable governmental regulations. Plant germplasm and transgenic material will not be made available except at the discretion of the owner and then only in accordance with all applicable governmental regulations.

CHAPTER 4. RESULTS

4.1 *Rps11* shows broad-spectrum resistance.

In an effort to identify novel sources of resistance to *P. sojae*, we identified a soybean landrace, PI 594527, possessing broad-spectrum resistance (Figure 4.1). A single *Rps* locus, *Rps11*, had been mapped onto chromosome 7 using a population derived from a cross between PI 594527 and Williams (*rps*) in our previous study (Ping *et al.*, 2016).

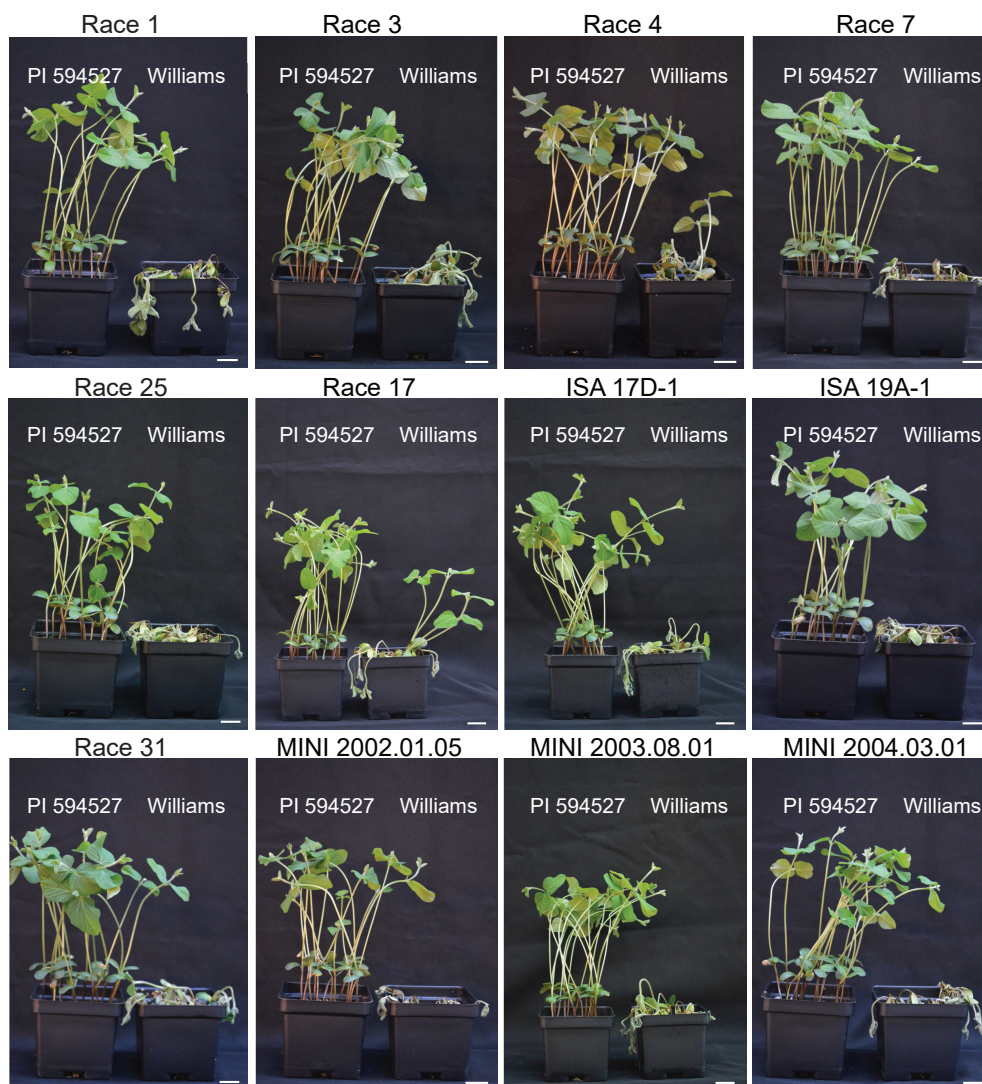

Figure 4.1 Resistance spectrum of PI 594527.

Table 4.1 Resistance spectrum of *Rps11* locus to 14 *P. sojae* isolate based on inoculation of a progeny population.

[illegible]

To confirm that the *Rps11* locus is solely responsible for the broad-spectrum resistance, we inoculated a subpopulation, including 14 progeny lines with *Rps11/Rps11* genotype (PI 594527) and 14 lines with *rps11/rps11* genotype (Williams), using 14 isolates of *P. sojae*. We observed perfect co-segregations between the presence/absence of *Rps11* and the phenotype after inoculation, suggesting that *Rps11* alone is responsible for the resistance in the donor line (Table 4.1). To further explore the resistance spectrum of *Rps11*, we inoculated a progeny line with *Rps11* using 158 additional isolates collected from all Indiana counties. We found that *Rps11* was resistant to 127 out of the 158 of these isolates (Figure 4.2 and Table 4.2). We also compared the resistance spectrum of *Rps11* with two novel Rps loci, *RpsUN1* and *RpsUN2*, previously identified in our lab. It shows that the spectrum of *RpsUN1*, *RpsUN2* and *Rps11* is significantly higher than the control line Williams (*rps*) ($P = 8.6 \times 10^{-46}$, 3.8×10^{-51} and 5.4×10^{-63} , respectively) (Figure 4.3). The spectrum of *Rps11* is also significantly higher than that of *RpsUN1* and *RpsUN2* ($P = 3.6 \times 10^{-6}$, 0.006, respectively) (Figure 4.3). Taken together, our results demonstrate that *Rps11* possesses a broad resistance spectrum to *P. sojae* and shows excellent potential in managing PRSR. Therefore, cloning of the resistant gene underlying *Rps11* will facilitate its deployment in soybean cultivars.

Figure 4.2 Distribution of the 158 isolates resistant or susceptible to *Rps11*. Green dots represent isolates that *Rps11* is resistant to, orange dots represent isolates that *Rps11* is partially resistant to, red dots represent isolates that *Rps11* are susceptible to.

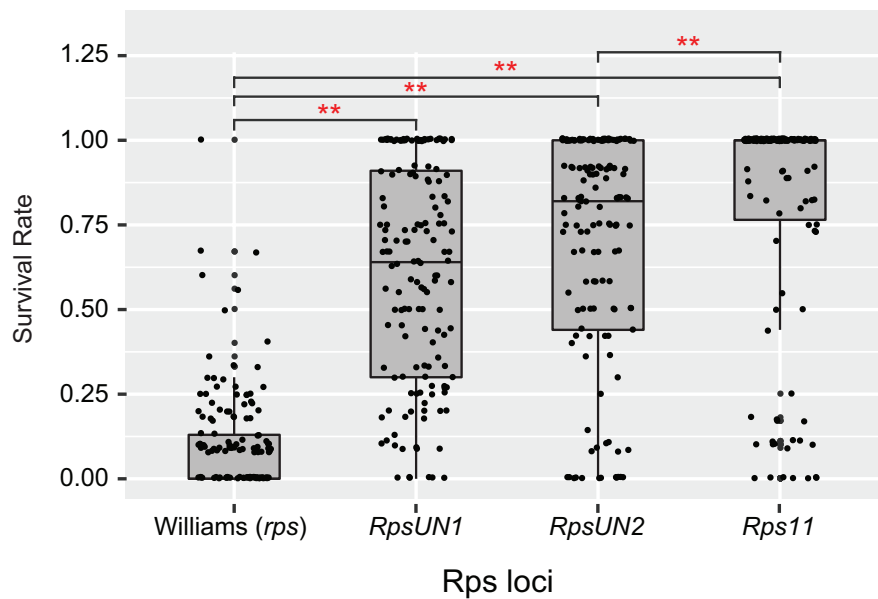

Figure 4.3 Resistance spectrum of *RpsUN1*, *RpsUN2* and *Rps11*. Red asterisks indicate significance level ($P < 0.01$).

Table 4.2 Resistance spectrum of *Rps11* to 158 *P. sojae* isolates collected from Indiana.

4.2 Genome sequencing of PI 594527 and NLR gene annotation.

Based on the responses of 209 F2:3 families derived from a cross between PI 594527 and a susceptible variety Williams to *P. sojae* Race 1, *Rps11* was initially mapped to a 348-kb genomic region on chromosome 7, with 12 sequencing gaps of unknown sizes according to the Williams 82 reference genome assembly v2.0 (www.soybase.org). In order to determine the correct genome structure and the copy number of NLR genes in the mapping region in the two parental lines, we performed whole genome sequencing and *de novo* assembly for PI 594527. The genome was built with 34 kb PacBio reads which were assembled into 424 contigs with a contig N50 of 13.8 Mb and further polished with Chromium 10X data. The contigs were scaffolded with 45 BioNano maps into 43 hybrid scaffolds with a scaffold N50 of 26.4 Mb, essentially 1-2 scaffolds per chromosome. Then, we performed NLR gene annotation across the entire genome and identified 512 NLR genes in total (Figure 4.4, Table 4.3, and Table 4.4).

Figure 4.4 Physical distributions of NLR genes across the PI 594527 genome.

Number of NLR genes was counted in 1-Mb sliding windows with 100-kb steps. y axis is the number of NLR genes and x axis is the soybean chromosomes. The arrow points the position of the NLR gene cluster in the *Rps11* region.

Chr20	45670091	45672685	Chr20_NLR_15

There are 12 NLR genes annotated in the *Rps11* region in the *Rps11* donor line. Among the twelve NLR genes, R2, R3, R5 and R8 are truncated with 2 to 4 exons lost at the 3' end; there is a 1.4 kb insertion in the first exon of R10, resulting in disruption of the NBS domain; The remaining seven NLR genes (R1, R4, R6, R7, R9, R11, and R12) are intact (Figure 4.5a), but only five (R1, R4, R6, R9, R12) are expressed based on the RNA-seq analysis (Figure 4.5b).

In order to figure out the correct genome structure and copy number of NLR genes in the susceptible parent, Williams, we obtained a sequence contig covering the *Rps11* corresponding region from Williams 82 assembly v3.0 (Chu et al., 2021), which was assumed to be the same as Williams at this region. Sequence comparison between the Williams 82 assembly v2.0 and v3.0 reveals a number of assembly errors in the *rps11* region in the Williams 82 assembly v2.0 (Figure 4.6). We then annotated the NLR genes in the *Rps11* corresponding region and identified only 8 NLR genes, dubbed r1 to r8, which have the similar gene models as R1-R12 in PI 594527 (Figure 4.7).

Figure 4.5 Gene models and expression pattern of the NLR genes in the *Rps11* region.

- a**, Gene models and alignments among twelve NBS-LRR genes in PI 594527. Black boxes represent exons of each NBS-LRR gene. Light-blue shades represent alignments.
- b**, Expression profile of the twelve NBS-LRR genes in the *Rps11* region. Y axis is the expression level (FPKM) based on RNA-seq data. The error bars represent standard errors.

Figure 4.6 Sequence comparison between Williams 82 assembly v2.0 and assembly v3.0.

Black boxes represent NBS-LRR genes and grey shades represent syntenic blocks between two versions. Red lines/dots represent sequencing gaps in the assembly v2.0.

Figure 4.7 Gene models of the 8 NLR genes in the *Rps11* corresponding region in Williams 82. Black boxes represent exons of each NBS-LRR gene. Light-blue shades represent alignments.

4.3 Fine mapping of the *Rps11* locus

Sequence comparison reveals only a small proportion of the *Rps11* region shared between PI 594527 and Williams 82 as syntenic blocks (Figure 4.8), which allowed us to design markers for fine mapping. To determine whether a single copy or a combination of multiple copies of the five expressed NLR genes was responsible for the broad resistance, we screened a total of 17,050 progenies using the boundary markers, SSR_286 and SSR_320, and identified 43 recombinants for finer mapping. We inoculated each recombinant with isolate Race 1 and designed additional markers within the NLR gene cluster at the syntenic blocks shared by the two parental lines. We eventually delimited *Rps11* to a 151-kb genome interval defined by Marker176 and InDel327, harboring 4 NLR genes (R5, R6, R7 and R8, Figure 4.9). Interestingly, R6 was the only expressed NLR gene within the final mapping interval, suggesting it was the best candidate responsible for the resistances (Figure 4.9). Furthermore, we examined the expression of the NLR genes in 9 key recombinants with different combinations of NLR genes. Recombinants with R1 expressed alone or a combination of R1 and R4 expressed together were susceptible, suggesting R1 and R4 do not confer resistance (Figure 4.10). Meanwhile, recombinants with a combination of R9 and R12 expressed together were also susceptible, which ruled out R9 and R12 (Figure 4.10). Only the recombinants with R6 expressed were resistant (Figure 4.10), further supporting R6 alone as responsible for the resistance. Then, we examined the expression pattern of R6 in different tissues and found it is also expressed in other tissues (Figure 4.11). The genomic DNA of R6, excluding

its regulatory sequences, is 14.1-kb, but it possesses a 13.1-kb 5' untranslated region (UTR) as determined by 5' Rapid amplification of cDNA ends (RACE) (Figure 4.12) and a 0.5-kb 3'UTR, totaling 27.7 kb (Figure 4.13). R6 is predicted to encode an NLR protein of 2,463 amino acids (Figure 4.13).

Figure 4.8 Comparison of the NLR gene clusters between Williams 82 and PI 594527.

Black boxes represent NLR genes and light-blue shades represent syntenic blocks between two genomes.

Figure 4.9 Fine mapping of the *Rps11* locus.

- Physical position of the *Rps11* locus on chromosome 7.
- Physical position of the markers used for fine mapping.
- Genotype and phenotype of the recombinants. The numbers in parentheses at left side are the number of recombinants with same haplotype. Green bars represent heterozygous genotype. Orange bars represent Williams genotype. Phenotype (survival rate after inoculation) of each recombinant type are shown at right side. H means heterozygous, S means susceptible. Numbers under each dashed line are the number of recombinants at each marker.
- NLR gene cluster in the *Rps11* region. Green bars represent expressed NLR genes. Grey bars represent non-expressed NLR genes.

Figure 4.10 Detection of the expression of the twelve NLR genes in each key recombinant. The phenotype of each recombinant is labeled. Y axis is expression level (FPKM) based on RNA-seq data.

Figure 4.11 Expression profile of *Rps11* in different tissues.
The error bars represent standard errors.

Figure 4.12 5' Rapid amplification of cDNA ends (RACE) performed for the 5 expressed NLR genes in PI594527.

x axis represents the distance upstream of the first exon. Brown bars represents the 5' RACE reads mapped to each NLR gene. Red lines/shades show the promoter regions sharing sequence similarity. Arrows at the right side indicate the direction of the NLR genes.

Figure 4.13 Gene model of *Rps11* (R6).

The vertical Arrow indicates the transcription start region (TSR). Orange color indicates the region encoding the NBS domain; Light-blue color indicates the regions encoding the LRR domains; Grey color indicates the region without a domain detected. Open boxes represent UTRs.

4.4 Functional validation of the *Rps11* candidate gene R6

To validate the function of R6, its CDS was synthesized and assembled with the ubiquitin promoter. We introduced the construct (pUbi:CDS-*Rps11*) into the soybean cultivar 93Y21, which is susceptible to *P. sojae* Races 25, 31 and OH12108-06-03. T₀ plants with a single copy of the insertion were obtained and advanced to the T₁ generation. The expression level of R6 in the homozygous T₂ transgenic lines was confirmed to be high and was not detected in non-transgenic lines (Figure 4.14). Segregating T₂ seedling families were inoculated with Race 25, 31 and OH12108-06-03. As exemplified in Figure 4.15, resistance to these three isolates in homozygous transgenic families was significantly increased compared to non-transgenic families (Figure 4.16), indicating R6 confers resistance to multiple isolates. Furthermore, we observed strong correlations between the expression levels of R6 and the resistance to all three isolates in T₂ families (Figure 4.17). These results demonstrate that R6 is responsible for the broad-spectrum resistance to *P. sojae* underlying *Rps11*.

Figure 4.14 Relative expression of the transgene (R6) in T₂ families

The error bars represent standard errors.

Figure 4.15 Photographic illustration of the resistance in two independent transgenic events. In each transgenic event, three homozygous T2 families, a non-transgenic line (Control), and a F₅ RIL (*Rps11/Rps11*) were inoculated. Scale bars = 2.5 cm.

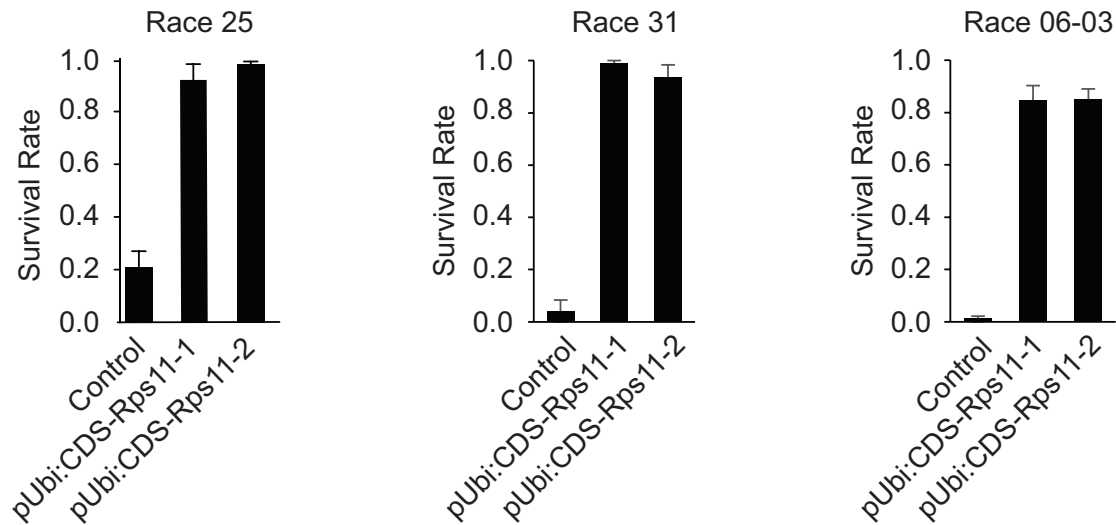

Figure 4.16 Statistics of the resistance test of homozygous T2 families compared with non-transgenic lines (Control). The Y-axis is the survival rate after inoculation. The error bars represent standard errors.

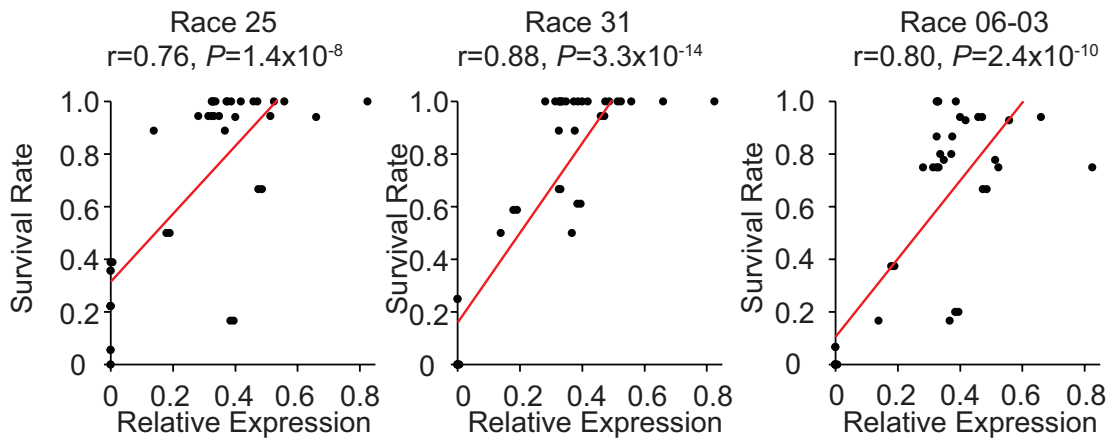

Figure 4.17 Correlation between the expression of R6 (Rps11) and the survival rate after inoculation in T2 population.

x axes are relative expression of R6, and y axes are survival rate after inoculation with Race 25 (left), Race 31 (middle), Race 06-03 (right).

4.5 Evolutionary history of *Rps11* and the NLR genes cluster in PI 594527

One of the most noticeable and unique features of the NLR genes within the *Rps11* region is their giant size. All intact NLR genes in this region have a CDS longer than 7 kb and a protein containing more than 2,000 amino acids (Figure 4.5a and Figure 4.7), larger than 97% of the soybean NLR genes and 99% of the NLR genes from 10 other plant species examined (Figure 4.18). Interestingly, all of these giant NLR genes clustered into the same clade on the phylogenetic tree (Figure 4.19), suggesting a single origin, which was echoed by the conserved gene models shared among all of the giant NLR genes (Figure 4.5a and Figure 4.7). To understand how the giant NLR genes reached this size, we compared the protein sequence of R6 with a typically sized NLR gene from the closest neighboring branch and found that the NBS domain was conserved between the giant NLR gene and the typically sized NLR gene (Figure 4.20). However, several rounds of tandem duplication were identified within the LRR region (Figure 4.20), suggesting the giant size of these NLR genes mainly resulted from tandem duplication of the LRR domains. Given that the NLR genes from both the *Rps11* region and its whole genome duplication (WGD) region (Chr16.R1) have similar sizes and gene models (Figure 4.21), the LRR tandem duplications must have occurred before the whole genome duplication ~13 million years ago (Doyle and Egan, 2010; Gill et al., 2009; Innes et al., 2008; Schmutz *et al.*, 2010).

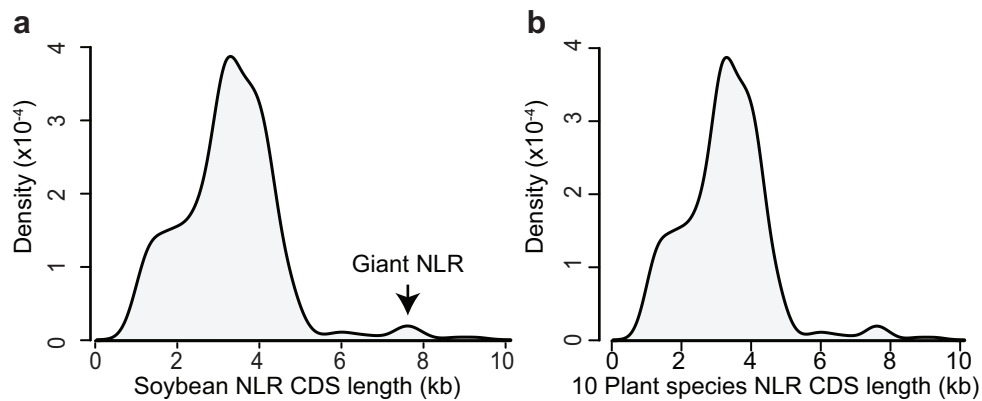

Figure 4.18 Distribution of CDS length in soybean genome and 10 representative plant species
10 plant species are Rice, Maize, Cotton, Common bean, Medicago, Apple, Peach, Banana, Tomato, Cucumber.

Figure 4.19 Phylogenetic tree of all the NLR genes in PI 594527 built using the conserved NB-ARC domain region.

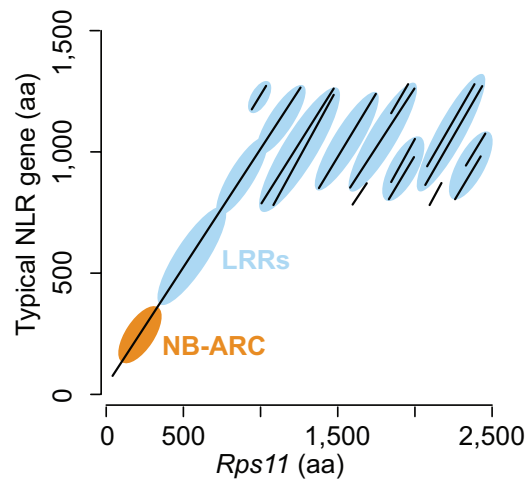

Figure 4.20 Comparison of protein sequences between a giant NLR gene and a typical NLR gene.

Lines represent the alignments between two protein sequences. Orange color highlights the NB-ARC domain region. Light-blue color highlights the LRR domain regions.

Figure 4.21 Gene model of Chr16.R1, the NLR in the WGD region of *Rps11*

The similar sizes and conserved gene models of the giant NLR genes suggested they were originally derived from a single gene. Given that only one NLR gene was found in its WGD region and the homologous region in common bean (Schmutz et al., 2014), this NLR gene cluster must have been formed after the WGD. To understand how this copy number variation evolved, we blasted the genome sequence from the *Rps11* region against itself, which revealed several segmental duplication events. First, R1-R2 were formed from a duplication of R3-R4, and then an inverted duplication event occurred to produce R11-R12 (Figure 4.22, D1), which was further supported by their relationship on the phylogenetic tree, where R1, R3 and R12 were grouped together, and R2, R4 and R11 were grouped together (Figure 4.23, D1). Second, R8 and R10 were formed by duplications of R7 (Figure 4.22, D2); Therefore, R7, R8 and R10 were grouped into the same clade on the phylogenetic tree (Figure 4.23, D2). All the NLR genes are likely derived from R5, because R5 is the closest to Chr16.R1 from the WGD region (Figure 4.13). In addition, the phylogenetic tree also revealed that R9 and R6 were derived from R11 and R3 respectively (Figure 4.23, D3 and D4). To summarize, the giant size of the NLR genes in the *Rps11* region stems from tandem duplications that occurred in the LRR domain of the original NLR gene prior to the WGD; The NLR gene cluster is mainly a result of segmental inversions and tandem duplication events after the WGD (Figure 4.24).

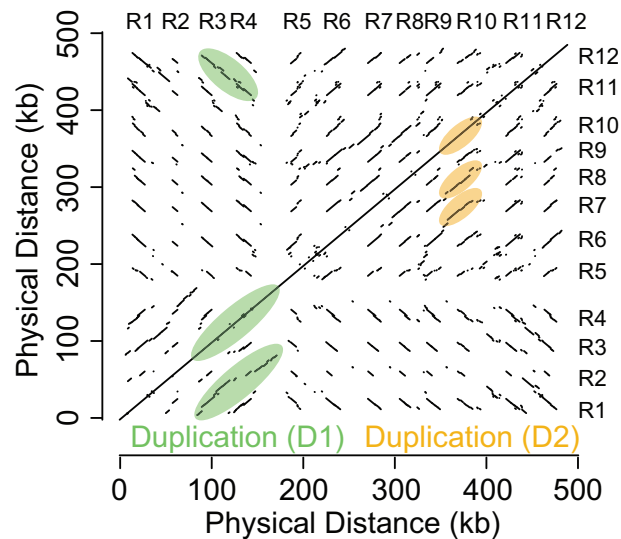

Figure 4.22 Dot plot of sequence comparison within the *Rps11* region in PI 594527.

Light-green color highlights the segmental duplication of R1-R2, R3-R4 and R11-R12 (Duplication 1, D1). Light-orange color highlights the segmental duplication of R7, R8 and R10 (Duplication 2, D2).

Figure 4.23 Phylogenetic relationship of all the NLR genes underlying *Rps11* and its WGD region.

Chr16.R1 is the NLR gene from *Rps11*'s whole-genome duplication region, constructed using transcript sequence. Background colors highlight the groups produced by each duplication event.

Figure 4.24 Illustration of the evolutionary history of the giant NLR gene cluster in the *Rps11* region.

Green boxes represent NLR genes and black boxes represent predicted non-NLR genes.

4.6 Complex diversification of the NLR gene cluster across 30 soybean genomes

To explore the diversification of the NLR gene cluster in the *Rps11*/*rps11* regions, we annotated the NLR genes for 28 additional soybean genomes (Liu *et al.*, 2020; Shen *et al.*, 2019; Shen *et al.*, 2018; Xie *et al.*, 2019). We identified a total of 316 NLR genes in the regions corresponding to *Rps11* across the 30 genomes (Table 4.5); Surprisingly, we observed drastic structural and copy number variations, ranging from 5 copies in SoyL09 to 23 copies in SoyC10. To examine if any of these genomes also carry *Rps11*(R6), we blasted the genome sequence from the *Rps11* donor line against all other genomes. Interestingly, none of them carried R6 in its entirety, with only SoyC03.R6 sharing high sequence similarity with R6 in the first ~10kb from the 5' end while being highly divergent from R6 in the remaining ~4kb at the 3' end (Figure 4.25).

Table 4.5 Information of NLR genes in the *Rps11* corresponding region across 30 soybean genomes.

^a Transcriptional Start Region.

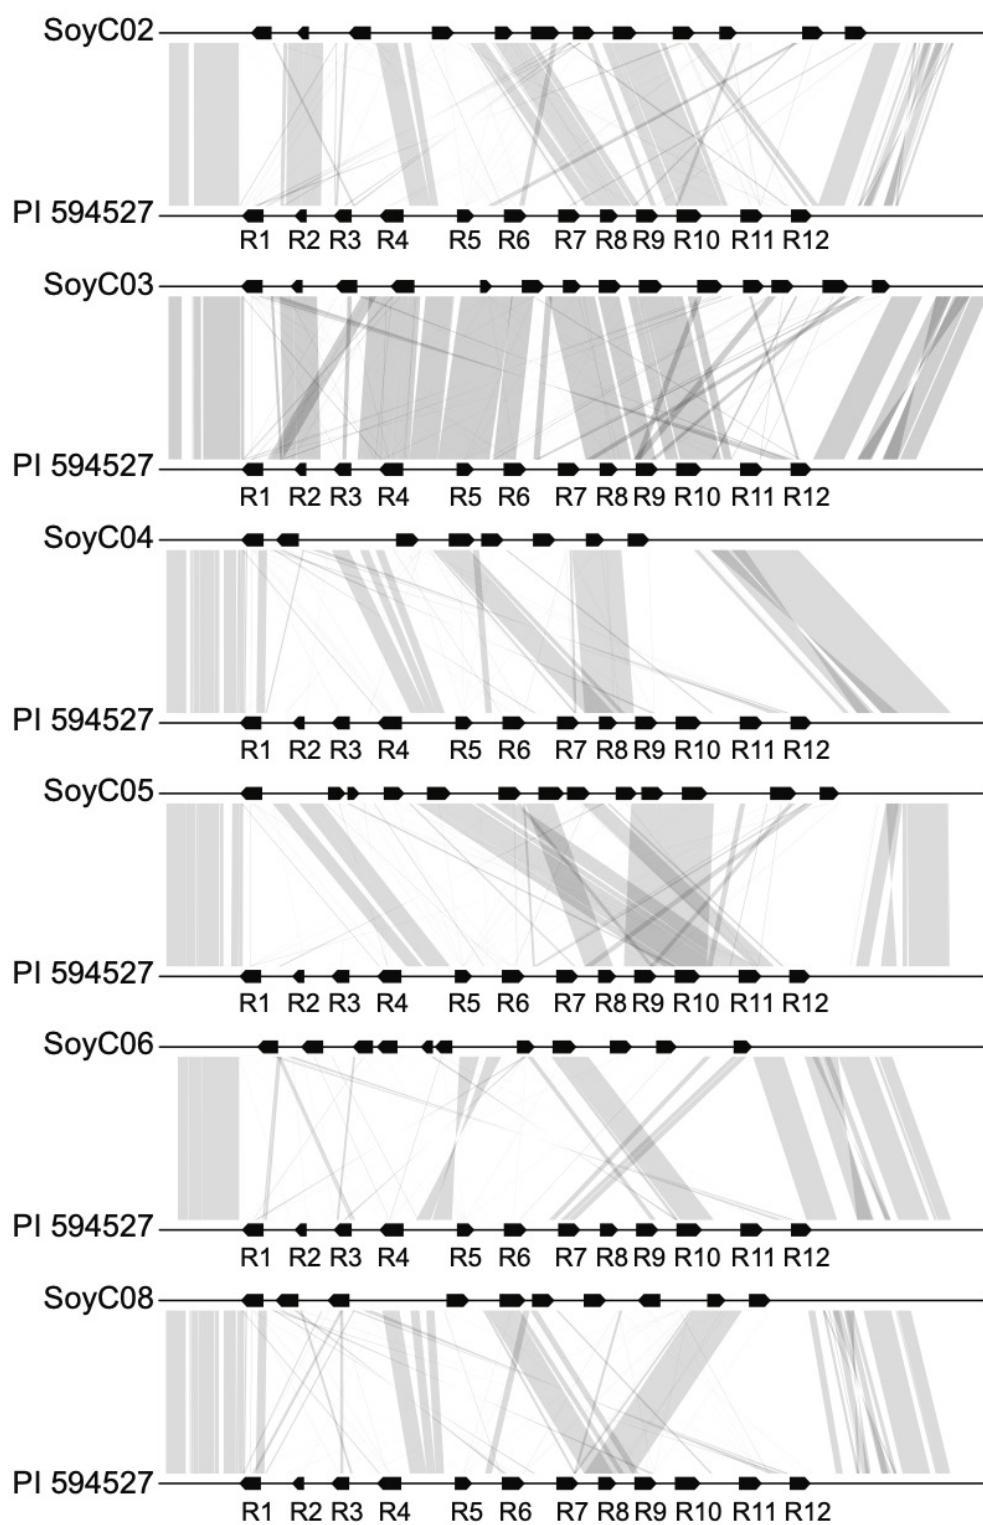

Figure 4.25 Sequence comparisons between PI 594527 and 29 additional soybean genome in the *Rps11*/*‘rps11’* region

Figure 4.25 continued

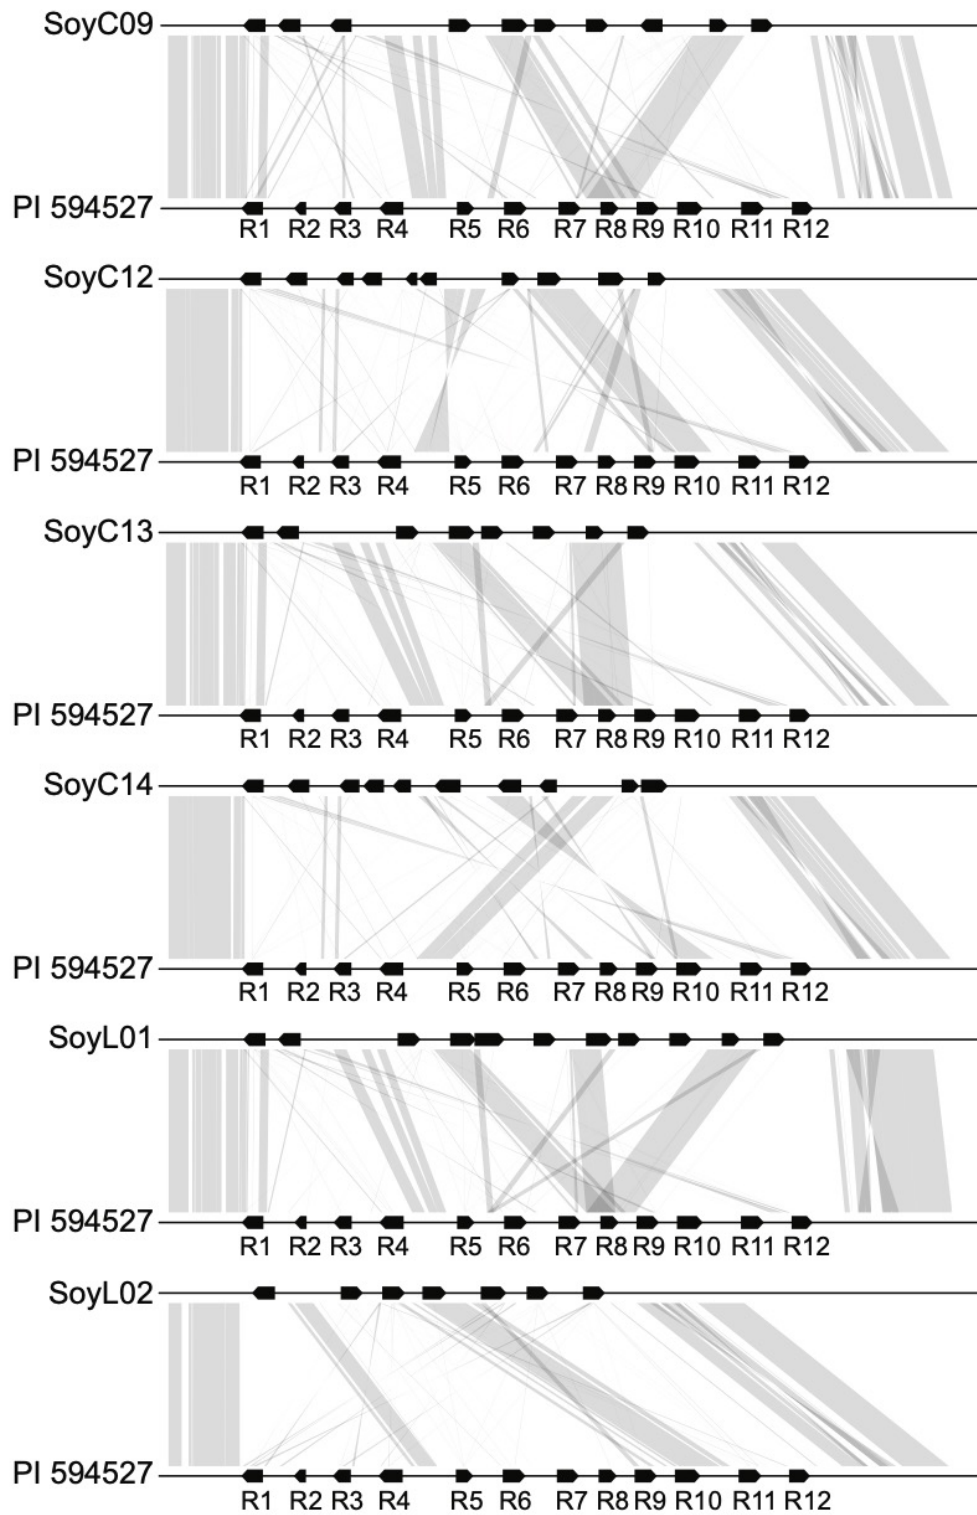

Figure 4.25 continued

Figure 4.25 continued

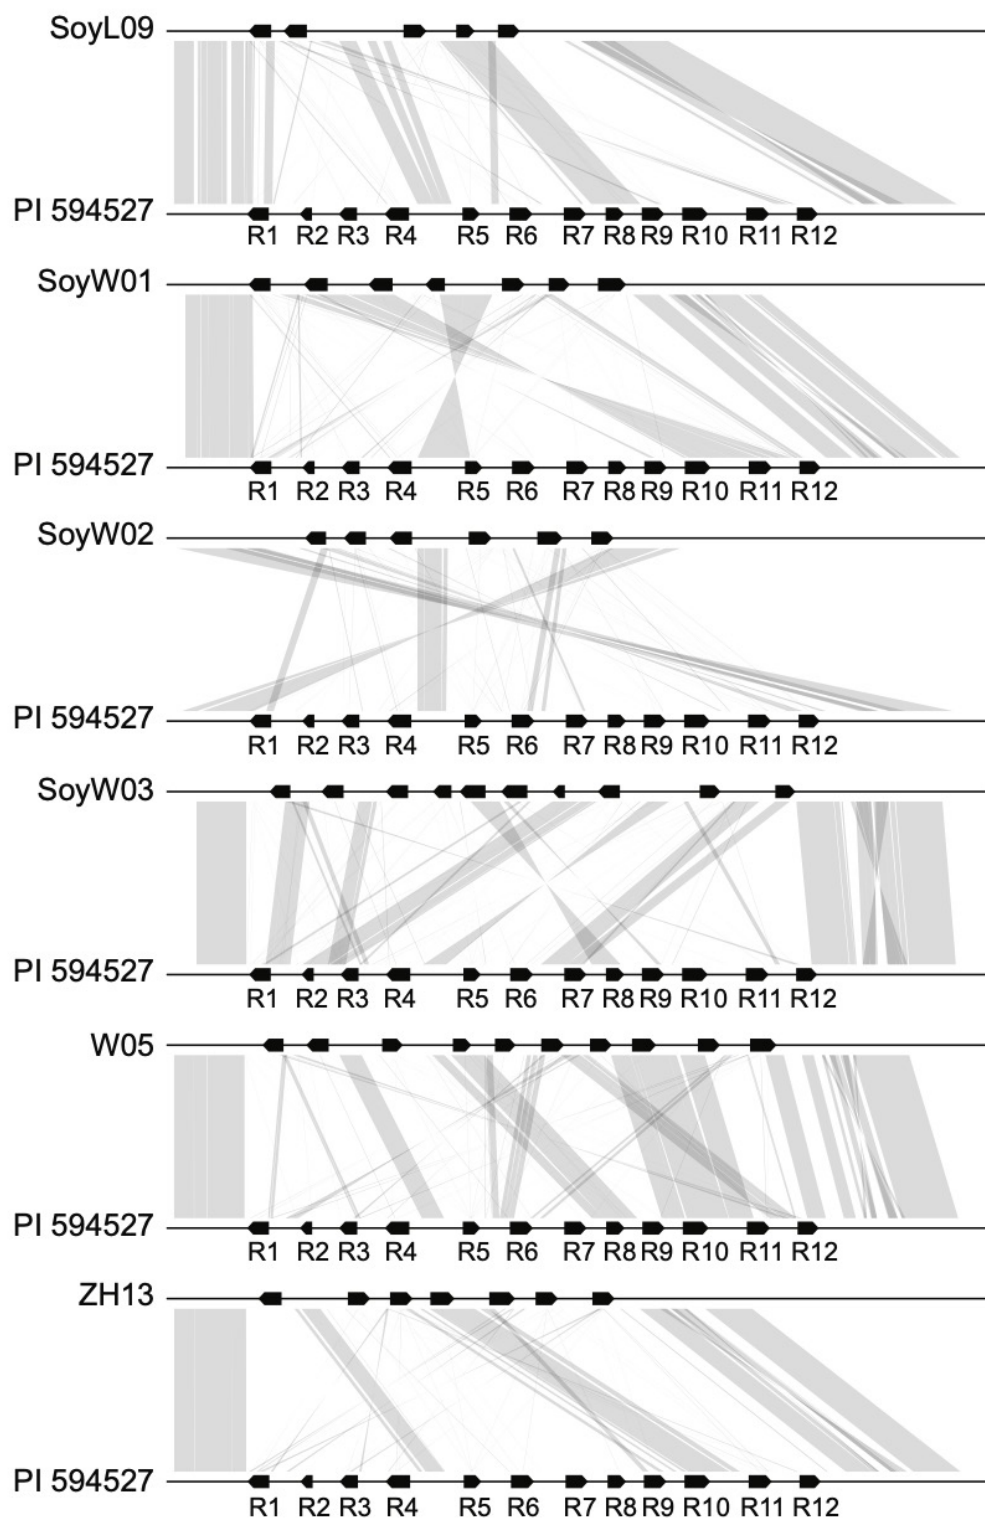

Figure 4.25 continued

Furthermore, we constructed a phylogenetic tree using the SNPs from the *Rps11* region and identified four major haplotype groups with high sequence similarity within but not between groups (Figure 4.26). Group I included SoyC06, SoyC12, SoyL06, SoyL07, SoyL08 and SoyC14; There was an inversion event within this group: R5-R6-R7-R8-R9-R10 in SoyC12 and SoyL06 was inverted from R10-R9-R8-R7-R6-R5 in SoyL07, SoyL08 and SoyC14 (Figure 4.26). In Group II, SoyC03 shared the highest sequence similarity with the *Rps11* donor line; SoyL04 and ZH13 share exactly the same haplotype with W05 and L02, respectively (Figure 4.26). Group III included SoyC07, SoyC01, SoyC11, SoyC10, SoyC02 and SoyL05. Several inversions and segmental duplications involving 2 to 5 NLR genes resulted in this group having the highest copy number (Figure 4.26). A deletion, potentially induced by unequal recombination, was detected between SoyC01 and SoyC07 (Box 1, Figure 4.26). Group IV shared a similar haplotype with the reference genome, Williams 82, with a tandem duplication event in SoyL01 induced by unequal recombination (Box 2, Figure 4.26). Taken together, our analyses revealed the complexity of the

NLR gene cluster across diverse soybean genomes and suggested that *Rp11* (R6) was unique to PI 594527. Cloning of *Rps11* will enable more precise selection of *Rps11* for cultivar improvement.

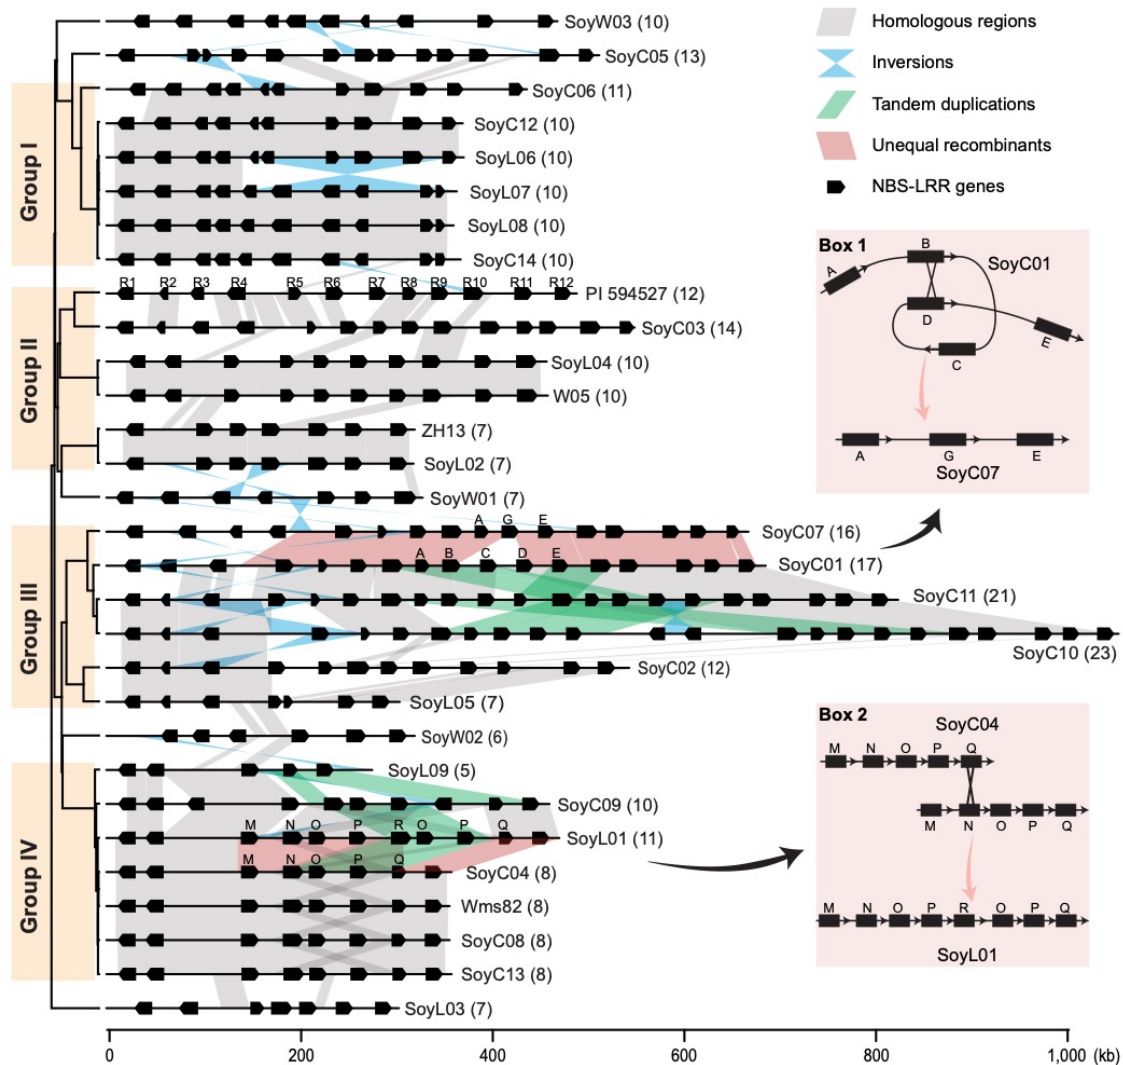

Figure 4.26 Diversification of the NBS-LRR gene cluster across 30 diverse soybean genomes.

The phylogenetic tree on the left side was built using SNPs data with the *Rps11* region. Orange color highlights the four major haplotype groups. Each black box represents an NBS-LRR gene. Grey shades represent syntenic blocks among genomes. Light-blue highlight inversion events. Green highlight tandem duplication events. Light-red highlight potential unequal recombination events. Box 1 and Box 2 exemplify a deletion and a duplication event induced by unequal recombination, respectively. The name of each genome was labeled at right side of each cluster and the numbers in parentheses are the total copy number of NBS-LRR genes in each genome at the *Rps11* corresponding region.

In addition to the structural and copy number variations, we also observed drastic variations in the expression levels of the NLR genes. While 97.8% (45 out of 46) NLR genes in the WGD region are expressed, only 59.8% (189 out of 316) of the NLR genes in the *Rps11* region are expressed (Table 4.5). To explain the expression differences of the NLR genes between the *Rps11* region and its WGD region and the variations within the *Rps11* region, we performed 5' Rapid amplification of cDNA ends (RACE) for the 5 expressed NLR genes in the *Rps11* region and Chr16.R1 in the WGD region in the *Rps11* donor line. We identified two independent transcription start regions (TSR), dubbed TSR1 and TSR2, at ~4kb and ~2.5kb upstream of Chr16.R1 (Figure 4.27a), both of which were found in every NLR gene in the WGD regions in all 29 genomes. Interestingly, only TSR2 was found in each of the 5 NLR genes in the *Rps11* region while TSR1 was completely absent, which might explain the significantly higher expression level of the NLR genes in the WGD region compared to those from the *Rps11* region (Figure 4.27b). Furthermore, we observed that the expression levels of NLR genes in the *Rps11* region were significantly associated with the presence/absence of TSR2 (Figure 4.27c), indicating that loss of TSR2 might be responsible for the expression variations of NLR genes within the *Rps11* region. By comparing the sequence of the *Rps11* donor line to the other genomes, we found that the *Rps11* promoter region shares high similarity with segments of the promoter regions of W05.R5 and W05.R6, indicating that an ancient unequal recombination event may have brought portions of R5 and R6 together to form the extremely long promoter region of *Rps11* (Figure 4.27d).

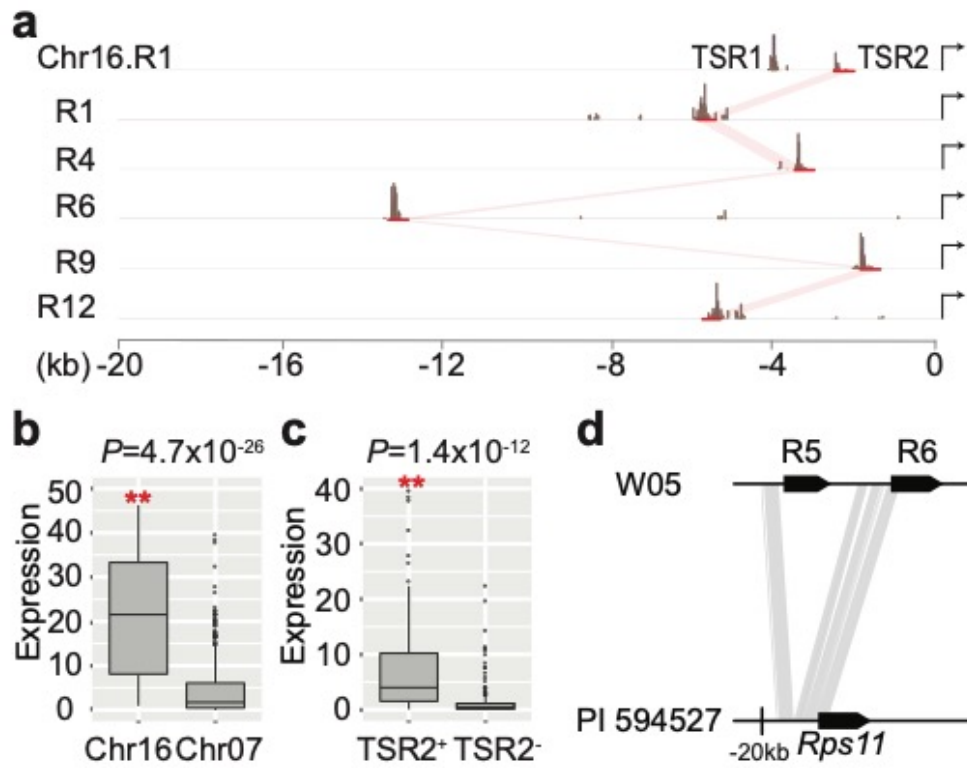

Figure 4.27 Analysis of the transcription start region of the NLR genes.

a, 5' Rapid amplification of cDNA ends (RACE) for the 5 expressed NBS-LRR genes (R1, R4, R6, R9 and R12) as well as the NBS-LRR gene at the WGD region (Chr16.R1). x axis represents the distance to the first exon. Brown bars represents the 5' RACE reads mapped to each gene.

b, Comparison of the expression levels of NBS-LRR genes from *Rps11* region (Chr07) and its WGD region (Chr16). Red asterisks indicate the significance.

c, Comparison of the expression levels of NBS-LRR with TSR2 (TSR⁺) and that without TSR2 (TSR2⁻) at the *Rps11* region. Red asterisks indicate the significance.

d, Sequence comparison of the promoter regions of *Rps11* and that of W05.r5 and W05.r6. Light-blue shades represent syntenic blocks.

CHAPTER 5. DISCUSSION

5.1 Significance of cloning the *Rps11* locus

In this study, we demonstrate that *Rps11* (R6), a ~27.7-kb NLR gene, confers broad spectrum resistance to *P. sojae*. Although Gao *et al.* claimed to have cloned *Rps1-k* (Gao and Bhattacharyya, 2008; Gao *et al.*, 2005), neither of the two NLR genes they reported were found in any versions of the genome assembly of Williams 82, which carries *Rps1-k*. Furthermore, the sequence contig used in their study was found to be an incorrect assembly of sequences from different chromosomes (Figure 5.1). The similarity between the two NLR genes identified by Gao *et al.* and the two closest NLR genes found in Williams 82 v3.0 is only around 95% (Figure 5.1). Therefore, the gene(s) underlying *Rps1-k* still remain unclear and *Rps11* is most likely the first gene cloned to confer resistance to *P. sojae*. PacBio sequencing was also shown to be much more powerful for assembling NLR gene clusters compared to short-read sequencing.

In addition, we found the NLR gene cluster was mainly formed by inversions and segmental tandem duplications after the WGD, some of which were induced by unequal recombination among different NLR genes. Unequal recombination has been proposed as a mechanism for creating novel resistance specificities (Hammond-Kosack and Jones, 1997; Hulbert, 1997; McHale *et al.*, 2006; Parniske *et al.*, 1997; Pryor and Ellis, 1993; Richter *et al.*, 1995), but high frequencies of unequal recombination also put the resistant gene at high risk of disruption. Precise isolation of the NLR gene underlying resistance will significantly accelerate its application in breeding programs towards effective management of PRSR.

Figure 5.1 Sequence comparison between the *Rps1-k* contig and the Williams 82 genome.

Black bars represent genome sequence of chromosome 3 (top), *Rps1-k* contig (middle) used for cloning, and chromosome 5 (bottom). Red bars represent NBS-LRR genes Light-blue shades represent alignments among different sequences.

5.2 Possible mechanisms underlying the broad resistance spectrum of *Rps11*

Sequence analyses suggested the giant size of *Rps11* is mainly a result of LRR tandem duplications which occurred before the whole genome duplication event in ~ 13 million years ago. The LRR domains in NLR genes are involved in determining the plant's ability to recognize specific pathogen effectors (McHale *et al.*, 2006). Whether the tandem duplications of the LRR domains found in *Rps11* are responsible for its broad resistance spectrum remains to be tested. Two possible mechanisms might explain the broad resistance spectrum of *Rps11*. First, the effector recognized by *Rps11* could be a conserved effector shared by a high proportion of the *P. sojae* population. Second, it is possible that *Rps11* recognize multiple effectors from different *P. sojae* isolates, which combine together responsible for the broad resistance spectrum of *Rps11*.

In this study, we have screened the *Rps11* locus with 158 isolates collected from fields across Indiana and identify 31 isolates that can defeat *Rps11*. Given that these isolates distributed across Indiana evenly, they might show high diversity. It would be interesting to sequence these isolates as well as a set of representative isolates that are not able to defeat *Rps11* to perform a genome-wide association study. If a single major association signal were detected, it is more likely that

Rps11 can recognize a single conserved effector from *P. sojae*. If multiple association signals were detected, it is more likely that *Rps11* can recognize different effectors. Sequence comparisons between the two categories of the isolates can help to isolate the effector gene(s) in *P. sojae* interacting with *Rps11*. One limitation of this genome-wide association study would be the small population size as well as the narrow genetic diversity of the tested isolates in this study since they were all collected from Indiana. Dorrance *et al.* has collected 213 unique isolates across eleven States across US (Dorrance et al., 2016), it would be more powerful if these isolates could be tested on *Rps11* and sequenced for identification of effector gene(s) interacting with *Rps11*.

5.3 Plant disease resistance not involving NLR genes

Besides disease resistance involving NLR genes, plants also have other different kinds of defense strategies when they are attacked by their own pathogens. In general, these resistances depend on either structural characteristics that can avoid the pathogens from entering and spreading in the plant cell and tissues, or biochemical reactions with products that can inhibit or kill the pathogens (Jones and Dangl, 2006). Most of the physical barriers are preexist. For example, the waxes on the surfaces of some plant leaves or stem can prevent pathogens from entering the plants. Some plants have very thick wall of epidermal cells which also important barriers to pathogens.

On contrast, biochemical defenses can be either preexist before infection or induced by pathogens. Some plants can produce one or more inhibitory compounds in young leaves, fruits, or seeds, for example phenolic compounds like tannins, or fatty acid-like compounds like dienes, and these compounds were proposed to play important roles in plant resistance. However, some toxic substances were produced by plants only when they are attacked by pathogens. Those pathogens can induce the expression of genes in plants to produce compounds that reduce the damage caused by the pathogens. All the resistances discussed above are nonspecific to a certain pathogen. They can prevent attacks from different pathogens. Transmembrane pattern recognition receptors of some plants, however, can recognize a specific pathogen by recognizing molecular patterns in the pathogen such as flagellin, which can trigger resistance reaction in plants.

Besides these natural resistance in plants. Engineered resistance is also very important, especially for crops (Salomon and Sessa, 2012). In addition to resistance genes, plants also have susceptibility

genes (S gene) that can facilitate the proliferation of pathogens. Genome editing on these susceptibility genes (for example using CRISPR/CAS9 to knock out these S genes) can also improve resistance of plants. Another good example of engineered resistance is pathogen-derived resistance. Transgenic over-expression of viral RNA can produce double strand RNA and eventually trigger RNAi to prevent the infection of virial pathogens (Voinnet, 2001).

5.4 Factors affecting durability of a R gene

Factors from both R gene side and pathogen side will affect the durability of a R gene. R genes with narrower resistance spectrum might be overcome faster because the pathogen isolates in a field changed over time due to quick evolution or long-distance spread. On contrast, R genes with wide resistance spectrum might interact with core effectors in the pathogen which shared by most isolates of the pathogens. Therefore, the duration of these R genes might be longer. R genes located at R gene enriched region (several copies of R gene at same locus) might be overcome faster because these R genes are easier to loss function due to mutations caused by unequal recombination. On contrast, R genes located at genome region with low mutation and recombination will be more stable. R genes with partners during recognition might be overcome faster because once their partner genes mutated, the recognition will also fail. Mutations on these partners will cause the loss of resistance of these R genes.

In order to maximize the durability of a R gene, we first need to select R genes with broad resistance spectrum, which means the R gene carries resistance to multiple strains of a pathogen. Therefore, it will not be easily defeated by a single strain. In addition, combination of different R genes will also dramatically increase the durability of resistance because it is less likely all the R genes are defeated simultaneously. We also need to regularly check the sequence of the R gene after deployment to make sure no mutations in the R gene occur.

From the pathogen side, it is very important to understand the virulence gene interacting with the R gene. So, we can check the diversity of the pathogen population in the field before deployment of the R gene to see if any pathogen strains carry virulence genes to the R gene. In addition, combining R gene with other means of disease control, such as chemical management, will also increase durability.

VITA

Weidong Wang

Department of Agronomy, Purdue University

West Lafayette, IN 47906

(a) Professional Preparation

China Agricultural University	Beijing, China	Agronomy	B.S. 2010
China Agricultural University	Beijing, China	Crop Genetics & Breeding	M.S. 2013
Purdue University	West Lafayette, USA	Agronomy	Ph.D. 2021

(b) Appointments

2014-2015 Graduate Research Assistant, Plant Biological Science Department, University of Minnesota-twin cities, MN, USA

2013-2014 Research Intern, Genetics Department, University of Wisconsin-Madison, Madison, WI, USA

(c) Honors and Awards

Graduate Research and Travel Award by Center for Plant Biology, Purdue University	2019
Outstanding Ph.D. Research Award by Agronomy Department, Purdue University	2018
George W. Bailey Travel Scholarship by Agronomy Department, Purdue University	2017
Dow AgroScience Graduate Scholarship, Agronomy Department, Purdue University	2017
George W. Bailey Travel Scholarship by Agronomy Department, Purdue University	2016
Top 10 Excellent M.S. Degree thesis award by China Agricultural University	2013
