## Approved by:

Dr. Dulcy Abraham

To my parents, Cindy and Jim, for all the love, support, and laughs for without which it would be a dull, confusing life.
To my brother, Ian, you and I already know you're awesome. Run fast.
To my uncle, Allen, for your quiet, calm mentorship and advice. Be good.
Finally, to my favorite idiots, Rory, Alfie, and MooMoo, for reminding me to cherish the small things and for making me smile every day.

## ACKNOWLEDGMENTS

First, I would like to express tremendous gratitude to my advisor, Dr. Darcy Bullock, for many years of guidance and support and for introducing me to transportation data analytics. I truly think it will change the world, and if by chance it doesn't, it certainly changed mine. Additionally, I would like to thank Dr. Jon Fricker and Dr. Nadia Gkritza for sharing their passion for and knowledge of transportation and for providing invaluable feedback that improved this study. Finally, I would be remiss not to not extend a massive thanks the many colleagues that mentored, taught, and assisted me along the way: Jairaj Desai, Dr. Jijo Mathew, Daniel Saldivar, Howell Li, Ben Scholer, Justin Mahlberg, Rahul Sakhare, and Woosung Kim.

#### Abstract

Historically, agencies have been reliant on physical infrastructure, crash data, manual data collection, and modeling to evaluate their road networks. Over the past several years, enhanced probe data has become commercially available and has shown itself to be a relatively inexpensive and scalable way to evaluate the performance of road networks. In January 2022 alone, 11.3 billion passenger vehicle trajectory waypoints and 279 million passenger vehicle event records were logged in the state of Indiana. This data, typically segmented into vehicle trajectory waypoints and vehicle event records, contains a variety of information including, but not limited to, location, speed, heading, and timestamp.

One use for this enhanced probe data is the evaluation of traffic signals for safety improvements. Typically, agencies require $3-5$ years of crash data to be able to statistically identify intersections in need of safety improvements. This study compared crash data over a 4.5year period at 8 signalized intersections to one month of weekday hard-braking and hardacceleration data from July 2019. A Spearman's rank-order correlation test was used, and a strong to very strong correlation between event data and crashes could be found indicating that just one month of event data could be an adequate substitute for $3-5$ years of crash data.

The representativeness of this data is often a major concern for many agencies as the usefulness of the data is only as good as the data itself. This paper describes and demonstrates a methodology for measuring connected vehicle penetration using data provided by state highway performance monitoring stations. This study looked at 1.7 billion count station vehicle counts and 70 million connected vehicle records across 381 count stations in 11 different states (California, Connecticut, Georgia, Indiana, Minnesota, North Carolina, Ohio, Pennsylvania, Texas, Utah, and Wisconsin). Across the 11 states and 381 stations, the average percent penetration was $3.8 \%$ in August 2020 and $3.9 \%$ in August 2021. Drilling down to August 2021, the percent penetration observed among the 187 interstate stations varied from $1.6 \%$ in Indiana to $10.0 \%$ in Wisconsin. A similar comparison of 162 non-interstate count stations showed a variation of $2.1 \%$ in MN and $18.0 \%$ in WI on non-interstates.

## 1. INTRODUCTION

Connected vehicle data is emerging as an important new data set for a variety of department of transportation (DOT) applications. One such example is the scalable evaluation of intersection performance measures. Removing the need for expensive infrastructure investments, connected vehicle data can provide several performance measures, such as arrival on green, downstream blockage, split failures, and level of service (E. Saldivar-Carranza et al., 2020). Similar analyses have been extended to include diverging diamonds and roundabouts (E. Saldivar-Carranza et al., 2022; E. D. Saldivar-Carranza et al., 2021). Another such use is the monitoring of highways for potential safety issues and safety improvements, especially within work zones. Studies using connected vehicle data have shown that speed feedback displays, digital speed limit trailers, presence lighting, and queue trucks have a positive impact on vehicle speeds and safety (Mathew et al., 2021; Sakhare, Desai, Mahlberg, et al., 2021; Sakhare, Desai, Mathew, et al., 2021). Additionally, as DOT's and legislatures look to the future of electric vehicles, connected vehicle data can provide a plethora of information regarding the usage of electric vehicles (Desai, Mathew, et al., 2021). Such information will be important in assisting decision makers with policy and infrastructure investments.

Crash data has historically been used to identify emerging safety issues at signalized intersections. However, collecting this data and implementing safety changes can take years. Event data, such as hard-braking and hard-acceleration data, has the potential to greatly reduce the data collection time. This thesis describes a use case for evaluating the correlation between crash data and hard-braking / hard-acceleration connected vehicle data and evaluates the relative penetration of connected vehicle data across 11 states. The remainder of this chapter and subsequent chapters are organized as follows:

- Chapter 1: Introduction and study motivation
- Chapter 2: Literature review
- Chapter 3: Background information on the study corridor
- Chapter 4: Crash data - introduction and analysis
- Chapter 5: Hard-braking and hard-acceleration event data - introduction and analysis
- Chapter 6: Correlation analysis between crash data and event data
- Chapter 7: Data representativeness evaluation across 11 states
- Chapter 8: Conclusion
- Appendix A: Data repository for connected vehicle penetration study
- Appendix B: Example percent penetration calculations for a station in each state

### 1.1 Study Motivation

The Indiana Department of Transportation (INDOT) has several ongoing projects that embrace the use of digital technologies. Such examples included the use of social media to alert road users of current road conditions, embedded weigh stations paired with roadside cameras to identify overweight trucks, and onboard truck telematics and real-time dashboards to assist with winter operations (Desai, Mahlberg, et al., 2021; INDOT, n.d.). However, identifying intersections in need of safety improvements remains an analog endeavor. Agencies are reliant on written crash reports which can be vague and dependent on witness accounts leaving the exact location unknown. Additionally, due to the relative infrequency of crashes, agencies need $3-5$ years of crash data in order to ensure the validity and accuracy of the agency's models. However, this method is considered reactive as agencies must wait for a substantial crash history to develop as evidence for proceeding with safety improvement projects. There is a growing interest in the industry to replace the historical method with surrogate events to reduce the time between data collection and the implementation of safety improvements.

Since the 1960 's, there has been interest in supplementing or replacing crash counts with traffic conflicts (Perkins \& Harris, 1968). Conflicts occur more frequently than crashes and are caused by the same failures that result in crashes (Tarko, 2020). The higher number of conflicts combined with their similar causations to crashes make them attractive to agencies trying to statistically determine areas for safety improvements. However, conflicts have a disadvantage; they can be difficult to collect, require trained personnel, and can be dependent on the subjective ratings of the observer.

Crowdsourced probe data that provides average segment speeds has been commercially available for some time (Remias et al., 2013). Recent developments of probe data now include data elements such as hard-braking and hard-acceleration from onboard sensors (Ctrl-Shift \& Wejo, 2020). This data, aggregated by third-party vendors, can provide agencies with the exact time and location of events on their roadways (Hunter, Saldivar-Carranza, et al., 2021).

In July 2019, there were over 6 million hard-braking events (Figure 1.1b) and over 10 million hard-acceleration events in Indiana. In contrast, during the same month, there were only 17,652 crashes in Indiana (Figure 1.1a), which represents $0.3 \%$ and $0.2 \%$ of the total number of hardbraking events and hard-acceleration events, respectively. In addition to the fewer number of crashes, crash reports may be incomplete or unclear. Between 2020 and 2021, 81.5\% of crash records were missing the roadway id and/or the mile marker. Event data, on the other hand, provides the exact time and location of the event. The motivation of this study is to use emerging crowdsourced event data for agency-wide screening of intersections and approaches for potential safety improvements, so agencies can follow up with mitigation measures addressing emerging problems much quicker than typical practices that rely on 3-5 years of crash data (Hunter, SaldivarCarranza, et al., 2021).

(a) In July 2019, there were 17,652 crashes in Indiana.

(b) In July 2019, there were $6,172,453$ hardbraking events in Indiana.

Figure 1.1. Visualization of number of events in Indiana in July 2019 (Hunter, SaldivarCarranza, et al., 2021)

## 2. LITERATURE REVIEW

This chapter presents a literature review on the current understanding of surrogate crash events and connected vehicle data. Understanding the current state of the practice was important in understanding where this study fit and developing ways to improve it.

### 2.1 Surrogate Crash Events

In the early years of traffic conflict analysis, a traffic conflict was defined as the occurrence of an evasive maneuver, braking, or a lane change (Older \& Spicer, 1976). Although there are many studies that analyze traffic conflicts, few have looked at hard-braking and hard-acceleration events at a large scale. Bagdadi and Varhelyi presented the critical jerk method to differentiate between critical and potentially critical events (Bagdadi \& Várhelyi, 2013). In a following paper, Bagdadi compared the critical jerk method to the longitudinal acceleration method in a naturalistic driving study focused on safety critical braking events. The study concluded that the critical jerk method was about 1.6 times better than the longitudinal acceleration method at identifying nearcrashes (Bagdadi, 2013). Stipancic, et al. compared hard-braking events and hard-accelerating events to crash frequency for links and intersections. For both hard-braking events and hardacceleration events, a positive correlation was found between the number of events and crash frequency for both links and intersections; however, the correlation was stronger for intersections (Stipancic et al., 2018). Li, et al. analyzed roughly 1.5 million crowd sourced hard-braking events at signalized intersections, work zones, interchanges, and entry/exit ramps. The study concluded that dilemma zones could be identified by hard-braking events along with work zones that may be in need of geometry changes or more advanced warning signs (Li et al., 2020).

Using video camera footage, Essa and Sayed concluded that the highest frequency of traffic conflicts occurred at the beginning of green as the queue is discharged at a low speed while vehicles joining the queue approach at a high speed; nevertheless, they considered most of these conflicts to be low-severity (Essa \& Sayed, 2019). While Mekker, et al.'s study focused on free flow and congested conditions on interstates, the study determined that a crash was approximately 24 times more likely to occur in congested conditions than in free-flowing conditions (Mekker et al., 2014). One common cause of congestion on interstates is construction activity. Desai, et al.
found that, in and around interstate work zones, there was approximately $1 \mathrm{crash} /$ mile for every 147 hard-braking events (Desai et al., 2020a).

Chapters 3-5 expand on a previously published paper looking at the relationship between hard-braking and crashes along SR-37. These chapters also consider hard-acceleration and add additional time bins to attempt to improve the correlation between hard-braking and hardacceleration events (Hunter, Saldivar-Carranza, et al., 2021).

### 2.2 Connected Vehicle Data

Connected vehicle data is just the latest in the evolution of vehicle data. As early as 1999, GPS based travel time data was used to evaluate agency infrastructure in Louisiana (Quiroga \& Bullock, 1998). By the early 2010s, crowdsourced vehicle probe data became available to both drivers and agencies through many providers and smartphone applications (INRIX, n.d.; Levine, 2019; Wang, 2007). While data gathered from smartphones was the main component to this crowdsourced data, some providers incorporated GPS-enabled vehicles as well (Hoseinzadeh et al., 2020; Kim \& Coifman, 2014). In the following years, many studies have been conducted to understand the accuracy of these datasets. These studies include a study conducted on 2,500 miles of roadway on and around I-95 evaluating commercially provided travel time and speed data (Haghani et al., 2009), a two-month study comparing probe data speeds to speeds obtained from loop detectors (Kim \& Coifman, 2014), studies comparing probe data to Bluetooth sensors with a focus on arterials and surface streets (Hoseinzadeh et al., 2020; X. Zhang et al., 2015), and a multiyear study comparing probe data to radar sensors (Ahsani et al., 2019).

These past iterations of vehicle data have been well tested and have been validated for many years. Connected vehicle trajectory data, which contains individual vehicle locations, timestamp, speed, and heading from onboard sensors, however, is still in the pilot phase for many agencies. Over the past several years, many studies focused on creating methodologies for evaluating road networks at low penetration. One study presented a method, tested against simulations and real-world data, for estimating queue length and traffic volumes without needing to explicitly know the market penetration (Zhao et al., 2019). A study conducted by Zhang et al. found that a $4 \%$ penetration was sufficient to improve ramp metering performance (C. Zhang et al., 2019). However, studies by Day et al. found that aggregated data at penetration levels as low
as $0.09 \%-0.8 \%$ would provide acceptable levels of representation for corridor retiming given a large enough aggregation period (Day et al., 2017; Day \& Bullock, 2016).

While connected vehicle data has led to the creation of new techniques to evaluate road networks (Desai et al., 2020b; Hunter, Saldivar-Carranza, et al., 2021; Li et al., 2019, 2020; Ma et al., 2020; E. Saldivar-Carranza et al., 2020; Waddell et al., 2020), there are few studies looking at connected vehicle penetration rates. In 2016, Li et al. compared loop detectors counts to vehicle trajectory counts and found an average percent penetration of $1.1 \%$ with a range of $0.2 \%$ to $2.0 \%$ depending on the time of day (Li et al., 2016). Chapter 7 of this paper expands upon two previous papers. The first paper analyzed the percent penetration for 3 months in 2020 in Indiana and found interstates to have an average percent penetration of $4.3 \%$ and non-interstates to have an average percent penetration rate of $5.0 \%$ (Hunter, Mathew, Cox, et al., 2021). The second paper extended the geographic analysis area to include Ohio and Pennsylvania and a total of 54 count station locations. The study found for August 2020, the average percent penetration ranged from $3.9 \%$ in Pennsylvania to $4.6 \%$ in Indiana (Hunter, Mathew, Li, et al., 2021). Utilizing a similar methodology, Chapter 7 continues to expand the number of count stations and number of states.

## 3. STUDY CORRIDOR

This study utilizes weekday event data collected between July 1 and July 31, 2019, at 8 intersections along a corridor on SR-37, south of Indianapolis, IN (Figure 3.1a, callout i). The corridor is a 4 to 6 -lane principal arterial with a speed limit of 55 mph . The volume along the corridor varies between 64,000 vehicles/day at the northernmost intersection, 49,000 vehicles/day in the middle of the corridor, and 38,000 vehicles/day at the southernmost intersection. Indianapolis commuters living south of the city use this corridor to commute northbound in the morning and southbound in the evening. The studied intersections (Figure 3.1b), in north to south order, are Thompson Rd., Harding St., Epler Ave., Southport Rd., Wicker Rd., County Line Rd., Fairview Rd. and Smith Valley Rd. These intersections run on an actuated-coordinated operation, most of them with a cycle length of 120 seconds, across four different weekday time-of-day (TOD) plans (Hunter, Saldivar-Carranza, et al., 2021):

AM Peak (AM): 05:00 - 09:15
Mid-day (MD): 09:15-14:30
PM Peak (PM): 14:30-19:00
Evening (EV): 19:00-22:00
An additional detail of note is that intersection 2, Harding St., in the southbound direction operates on a contestant green signal.

Figure 3.1. Corridor location for hard-braking and hard-acceleration event study

The number of vehicle trajectories along the corridor varies between 823 trajectories/day at the northernmost end, 414 trajectories/day in the middle, and 472 trajectories/day at the southernmost end. Figure 3.2 presents the number of weekday trajectories to traverse each intersection by movement type in July 2019. Noticeably, the vast majority of vehicles travel straight through the intersections instead of turning. Additionally, intersections 4 and 5 stand out as having the most cross traffic (Figure 3.2c and Figure 3.2d).

Figure 3.2. Number of weekday trajectories to enter the intersections by movement type for July 2019

## 4. CRASH EVENTS

### 4.1 Crash Data

The crash counts were aggregated by intersection using information gathered from Indiana's online crash repository. Using the provided GPS information, crashes that were located along the corridor within 1320 ft of an intersection were assigned to that intersection. Crashes that were missing geolocation information were manually assigned to intersections on the study corridor, if applicable, by reading through the crash report's narrative. Crashes were then filtered by their different attributes, such as their recorded manner of collision, direction of travel, and time of day.

In Indiana, during July 2019, 17,652 crashes were reported, of which 24 occurred along the roughly 6.5 -mile study corridor. 10 of those 24 crashes occurred in the vicinity of an intersection. As agencies need $3-5$ years of crash data in order to have enough crash data to perform a statistical correlation test, this study collected crash data for a 4.5 -year period between January 1, 2016 and July 9, 2020. This increased the intersection crash count to 551 crashes, of which 391 were weekday crashes. Of the 391 weekday crashes, 261 of those indicated a rear-end collision and 24 indicated a right-angle collision (Hunter, Saldivar-Carranza, et al., 2021).

### 4.2 Analysis: Crash by Manner of Collision

Figure 4.1 shows a stacked bar graph of the number of crashes categorized by manner of collision that occurred adjacent to the 8 intersections along SR-37 on weekdays during the 4.5year study period. The southbound approach of intersection 4, Southport Rd., stands out as having the most crashes ( 71 crashes) for the 4.5 -year period. Of those 71 crashes, $70 \%$ were rear-end collisions. Likewise, the second and third highest crash count approaches, southbound intersection 5, Wicker Rd., and northbound intersection 8, Smith Valley Rd., have 75\% and 65\%, respectively, of their total crash count as rear-end crashes. Overall, $65 \%$ of the 391 recorded weekday crashes on this corridor were rear-end collisions. Right-angle collisions were less frequent and only accounted for 24 of the 391 weekday crashes ( $6 \%$ ), with the most right-angle collisions occurring at intersection 4, Southport Rd. (2 in NB and 7 in SB), and intersection 6, County Line Rd. (4 in NB and 3 in SB) (Hunter, Saldivar-Carranza, et al., 2021).

(a) Northbound
(b) Southbound

Figure 4.1. Number of weekday crashes by intersection and manner of collision on SR-37 between January 1, 2016 and July 9, 2020 (Hunter, Saldivar-Carranza, et al., 2021)

### 4.3 Analysis: Crashes by Time of Day

Figure 4.2 presents a heatmap of weekday crashes aggregated over the study period. Crashes were binned by 30 -minute periods and assigned to their respective intersections. In the southbound approach (Figure 4.2b), intersection 4, Southport Rd., and intersection 5, Wicker Rd., stand out in the PM time frame as having a relatively large number of crashes (Hunter, Saldivar-Carranza, et al., 2021).

Figure 4.2. Heatmap of frequency of weekday crashes between January 1, 2016 and July 9, 2020 (Hunter, Saldivar-Carranza, et al., 2021)

## 5. EVENT DATA: HARD-BRAKING AND HARD-ACCELERATION

### 5.1 Data

The event data used in this study was made commercially available by a data provider that works directly with the original equipment manufacturers (OEMs). The enhanced probe data from these connected passenger vehicles included an anonymized unique identifier along with timestamp, geolocation, speed, heading, and event description, such as hard-braking/acceleration (Note: Connected vehicles, in this paper, are defined as any vehicle that sends information to another vehicle, a roadside unit, or it's manufacturer). The provider of this data defined hardbraking and hard-acceleration events as any vehicle deceleration or acceleration with a magnitude greater than $8.76 \mathrm{ft} / \mathrm{s}^{2}(0.272 \mathrm{~g})$. In July 2019, over 6,000 hard-braking events occurred along SR37 within 1320 ft of the 8 intersections. Likewise, over 11,000 hard-acceleration events occurred. The penetration level of this data is estimated to be around $2 \%$ (Hunter, Saldivar-Carranza, et al., 2021).

### 5.2 Methodology

The events analyzed in this paper were sorted by intersection, distance from stop bar, and speed at which the vehicle was traveling when the event occurred. In this study, the analysis was limited to through movements. A geofence region was drawn along the through lanes for each approach. This upstream region began parallel to the opposing direction's stop bar and ended 1320 ft , a quarter mile, upstream. Once the geofenced region was defined, the events that occurred within those regions were selected, and the GPS location of each event was compared to the location of the stop bar in order to calculate the distance from stop bar. Figure 5.1a shows the hardbraking events for an intersection along the study corridor. Figure 5.1b shows the upstream geofence regions and the geofenced hard-braking events color coded by speed. The 400 ft boundary, relative to the stop bar, roughly corresponds to the location of the dilemma zone detectors at this intersection (Gazis et al., 1960; Hunter, Saldivar-Carranza, et al., 2021; Parsonson, 1978; Zegeer \& Deen, 1978).

(a) Approximately 3,000 hard-braking event points around the intersection of SR 37 and \#4 Southport Rd.

(b) Approximately 1,600 hard-braking points captured by the north and southbound upstream geofence regions. Hard-braking event points are colorized by speed of vehicle at the time of the event.

Figure 5.1. Visualization of event processing (Hunter, Saldivar-Carranza, et al., 2021)

### 5.3 Hard-Braking

### 5.3.1 Analysis: Hard-Braking Events by Distance

The hard-braking events are classified by their distance from the stop bar to study the impact of dilemma zone (Gazis et al., 1960; Parsonson, 1978; Zegeer \& Deen, 1978) and queuing. Type II dilemma zone has been defined in previous literature as the road segment where there is a $10 \%-90 \%$ probability of a vehicle stopping at the beginning of the yellow light (Parsonson, 1978). The occurrence of hard-braking events less than 400 ft (location of advance detector upstream of stop bar at 55 MPH speed limit zone) from the stop bar at lower speeds are possibly due to vehicles stopping for the red light, whereas such occurrences at higher speeds could be due to dilemma
zone issues. Hard-braking events occurring at distances greater than 400 ft from the stop bar are potentially due to long queues during oversaturated conditions.

Figure 5.2 shows the number of weekday hard-braking events occurring at each intersection, stacked by distance from the stop bar, aggregated over the month of July 2019. For both northbound and southbound approaches, the majority of the hard-braking events occur within 400 ft of the stop bar $(73 \%)$. However, there are a few intersections (\#8 Smith Valley Rd., in NB and \#4 Southport Rd. and \#5, Wicker Rd. in SB) where more than $40 \%$ of hard-braking events occurred more than 400 ft from the stop bar (Hunter, Saldivar-Carranza, et al., 2021). Additionally, comparing the number of trajectories to pass through each intersection in the northbound and southbound directions (Figure 3.2a and Figure 3.2b) and the number of hard-braking events by intersection reveals that the number of hard-braking events is not directly related to the number of trajectories of the same direction. However, there may be a positive relationship between the number of trajectories to pass through each intersection in the eastbound and westbound directions (Figure 3.2c and Figure 3.2d) and the number of hard-braking events by intersection. For example, southbound intersection 4, Southport Rd., has the most hard-braking events but is far from having the most trajectories in the northbound or southbound directions. However, southbound intersection 4, Southport Rd., does have the greatest number of cross street trajectories.

Note: Stop bar is located at 0 ft .
Figure 5.2. Number of weekday hard-braking events by intersection and distance from stop bar

To understand the temporal nature of the hard-braking events and their distances from the stop bar, a heatmap was generated. Figure 5.3 illustrates a heatmap of the number of hard-braking events, during weekdays in July 2019, on the northbound approach over a 24 -hour period (30minute bins) across two distance categories - less than 400 ft and greater than 400 ft . For the less than 400 ft category, the majority of hard-braking events occur during the AM, MD and PM plans (Figure 5.3a), with no clear pattern or trend. For the 400 - 1320 ft range (Figure 5.3b), there are generally fewer hard-braking events, except for perhaps intersection 8, Smith Valley Rd, during the PM plan.

Figure 5.4 shows a heatmap similar to Figure 5.3, for the southbound approach. Hardbraking events within 400 ft of the intersection (Figure 5.4a) are generally higher for the PM plan, especially at intersection 8, Smith Valley Rd. Figure 5.4b, which is comprised of events occurring
beyond 400 ft , shows a different pattern than the northbound approaches. Intersection 4, Southport Rd., and intersection 5, Wicker Rd., experience a large number of hard-braking events during the PM plan. This could be indicative of hard-braking events that occur at the back of long queues during the PM peak period (Hunter, Saldivar-Carranza, et al., 2021).

(a) Between 0 and 400 ft upstream of the stop bar

(b) Greater than 400 ft upstream of the stop bar

Figure 5.3. Heatmap of weekday hard-braking events by intersection for northbound SR-37, in July 2019

Figure 5.4. Heatmap of weekday hard-braking events by intersection for southbound SR-37, in July 2019

### 5.3.2 Analysis: Hard-Braking Pattern by Intersection

To further investigate the pattern of hard-braking events, a histogram of the events stacked by speeds were plotted for different time of day plans over their distance from the stop bar. Figure 5.5 and Figure 5.6 present two such patterns for weekdays between 5:00 AM and 10:00 PM in July 2019.

Figure 5.5 shows the hard-braking events at the southbound approach of intersection 4, Southport Rd. During the PM time plan (Figure 5.5b), hard-braking events are occurring consistently for the entirety of the quarter-mile from the stop bar, with very few of those hard-
braking events occurring at speeds over 45 mph . The aerial image in Figure 5.5 a shows that there are no driveways or bus stops in the region that could be contributing to these hard-braking events.

Figure 5.6 shows the hard-braking events at the southbound approach of intersection 8, Smith Valley Rd. The PM plan, (Figure 5.6b), stands out as having numerous hard-braking events within the $0-400 \mathrm{ft}$ region. In some of the speed bins around 250 ft upstream of the intersection, over $60 \%$ of those hard-braking events occur at speeds above 45 mph which could indicate dilemma zone issues. Dilemma zone protection is often difficult on coordinated movements as more phases compete for green time and coordinated phases are forced off (Hunter, SaldivarCarranza, et al., 2021).

Figure 5.6. Southbound approach, SR-37 at Smith Valley Road (Intersection 9)

### 5.4 Hard-Acceleration

### 5.4.1 Analysis: Hard-Acceleration by Distance

As with hard-braking, the hard-acceleration events are first classified by their distance from the stop bar. Figure 5.7 shows the number of weekday hard-acceleration events occurring at each intersection, stacked by distance from the stop bar, aggerated over July 2019. Similar to hardbraking, a large portion of hard-acceleration events occurred between the stop bar and 400 ft upstream ( $51 \%$ ). However, while a negligible number of hard-braking events occurred downstream of the stop bar, over $40 \%$ of hard-acceleration events occurred past the stop bar. Additionally, a disproportionate number of hard-acceleration events, almost $30 \%$, occurred at intersection 1, Thompson Rd. Like hard-braking, the number of hard-acceleration events did not directly trend with the number of trajectories traveling in the northbound and southbound directions (Figure 3.2a and Figure 3.2b). However, unlike hard-braking, no discernable pattern is apparent between the number of hard-acceleration events and the number of trajectories in the eastbound and westbound directions (Figure 3.2c and Figure 3.2d) either.

Note: Stop bar is located at 0 ft.
Figure 5.7. Number of weekday hard-acceleration events by intersection and distance from stop bar

Temporal heatmaps were also generated for hard-acceleration events. While the hardbraking heatmaps focused on the specific location of the even upstream of the stop bar, these hardacceleration heatmaps are divided by events occurring downstream of the stop bar (-200 - 0 from the stop bar) and upstream of the stop bar ( $0-1320 \mathrm{ft}$ from stop bar). Figure 5.8 and Figure 5.9 show the number of hard-acceleration events, during weekdays in July 2019, for the northbound and southbound approaches, respectfully. In the northbound direction, no pattern stands out in the downstream region (Figure 5.8a); however, in the upstream region, intersection 1, Thompson Rd., stands out has having more hard-acceleration events than other intersections throughout the daylight hours (Figure 5.8b). In the southbound direction, the downstream region, as with the northbound direction, has no major discernable pattern (Figure 5.9a). Upstream of the stop bar in
the southbound direction, however, has a clustering of hard-acceleration events in the PM time period at intersection 1, Thompson Rd., intersection 4, Southport Rd., intersection 5, Wicker Rd., and intersection 8, Smith Valley Rd. (Figure 5.9b).

(a) Downstream of the stop bar

(b) Upstream of the stop bar

Figure 5.8. Heatmap of weekday hard-acceleration events by intersection for northbound SR-37, in July 2019

Figure 5.9. Heatmap of weekday hard-acceleration events by intersection for southbound SR-37, in July 2019

### 5.4.2 Analysis: Hard-Acceleration Pattern by Intersection

Further replicating the hard-braking study with hard-acceleration, histograms of events stacked by speeds, plotted for different time of day plans, over their distance from the stop bar were created. Figure 5.10 shows an example of these plots.

Figure 5.10 shows the hard-acceleration event pattern for the southbound approach of intersection 1, Thompson Rd. Perhaps, unsurprisingly, the majority of hard-acceleration events regardless of time of day occur just before the stop bar or just after the stop bar (Figure 5.10b). Additionally, the vast majority of these events are occurring at speeds less than 30 mph . This could indicate that vehicles are rapidly accelerating as the signal turns to yellow or even red which could
further indicate a dilemma zone issue and/ or an eagerness to accelerate after the light has turned green.

## 6. CORRELATION: EVENT DATA AND CRASHES

### 6.1 Hard-Braking and Rear-End Collisions: 30 Minute Bins

In addition to the graphical visualizations highlighting similar patterns between crashes and events, several correlation tests are performed to determine if a linear correlation is present. In the first correlation test, the aggregated July 2019 weekday hard-braking events occurring over a 30minute period are compared with the aggregated 4.5-year period rear-end crashes occurring over the same 30-minute period (Hunter, Saldivar-Carranza, et al., 2021). Rear-end collisions were the focus of this first correlation test due to the fact that the vast majority of collisions at intersections along this corridor were rear-end collisions. Additionally, hard-braking and rear-end collisions are intuitively related; A common reaction to approaching a vehicle and sensing a collision is to slam on the brakes.

### 6.1.1 Correlation Test

A simple Spearman rank order correlation test (Spearman, 1904) is conducted to evaluate the monotonic relationship between a pair of data. The correlation coefficient, $r_{s}$, represents the strength of that relationship. There are many interpretations in the literature (C.P \& J., 2007; Y.H., 2003) on coefficient thresholds, but this study utilizes a conservative interpretation suggested by Evans (Evans, 1996) as seen in Table 6.1.

Table 6.1. Spearman: Interpretation of Correlation Coefficient

| Correlation Coefficient | Correlation Significance |
| :---: | :---: |
| $0.80-1.0$ | Very Strong |
| $0.60-0.79$ | Strong |
| $0.40-0.59$ | Moderate |
| $0.20-0.39$ | Weak |
| $0.00-0.19$ | Very Weak |

Table 6.2 and Table 6.3 show the results of the Spearman test conducted at $95 \%$ and $99 \%$ confidence levels and highlights intersections with a strong correlation, for northbound and southbound respectively. Results indicate a strong correlation between rear-end crashes and hardbraking events past 400 ft of the stop bar at northbound intersection 8, Smith Valley Rd., and
southbound intersection 4, Southport Rd., and intersection 5, Wicker Rd. A check in the strong correlation box is used if the $r_{s}$ value exceeds the 0.6 threshold shown in Table 6.1.

Interestingly, while southbound intersection 8, Smith Valley Rd. experienced a high number of high-speed hard-braking events within 250 ft of the stop bar (Figure 5.6b), this location does not exhibit a strong correlation to rear-end crashes as suggested by prior conflict models (Hunter, Saldivar-Carranza, et al., 2021; Sharma et al., 2011).

* Significant at 99\% Confidence Level
** Significant at 95\% Confidence Level

### 6.1.2 Sensitivity Analysis

To determine if one month of hard-braking event data is sufficient to suggest a reasonable correlation between hard-braking events and crashes, a sensitivity analysis using Spearman's correlation is performed. While this study primarily uses one month of hard-braking data collected from July 2019, the sensitivity analysis includes data from July and August 2019. Figure 6.1 shows the results of this analysis. The two plots in Figure 6.1 show that the $r_{s}$ values plateaus around 4 weeks' worth of data. This suggests that one month of hard-braking data is sufficient to result in a reliable correlation with over 4.5 years' worth of crash data (Hunter, Saldivar-Carranza, et al., 2021).

Figure 6.1. Sensitivity analysis for Spearman correlation between hard-braking events and rearend crashes for 8 weeks in July and August 2019

### 6.2 Event Data and Collisions: A Better Fit

Next, the study compared different time bins, types of crashes, and the relationship between hard-acceleration and crashes to determine if a better correlation could be achieved. Table 6.4 and Table 6.5 show the results of this comparison. Table 6.4 presents the number of intersections to have a strong or very strong correlation between hard-braking and all collisions and specifically rear-end collisions for both directions and three distance regions: $0-400 \mathrm{ft}, 400-1320 \mathrm{ft}$, and 0 - 1320 ft . Overall, binning hard-braking and crashes in 3-hour time bins was the most affective in achieving a strong or very strong correlation between collisions and hard-braking events. In the southbound direction, in the 3-hour time bin, all 8 intersections had a strong or very strong correlation between rear-end collisions and hard-braking events occurring in the 0-1320 ft region.

Table 6.4. Number of intersections to have a strong or very strong correlation between hardbraking events and collisions for different time bins

|  | NB |  |  |  |  | SB |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} 15 \\ \text { Min } \\ \hline \end{gathered}$ | $\begin{gathered} 30 \\ \text { Min } \end{gathered}$ | $\begin{gathered} 1 \\ \text { Hour } \end{gathered}$ | $\begin{gathered} 2 \\ \text { Hour } \end{gathered}$ | $\begin{gathered} 3 \\ \text { Hour } \end{gathered}$ | $\begin{gathered} 15 \\ \text { Min } \end{gathered}$ | $\begin{gathered} \text { 30 } \\ \text { Min } \end{gathered}$ | $\begin{gathered} 1 \\ \text { Hour } \end{gathered}$ | $\begin{gathered} 2 \\ \text { Hour } \end{gathered}$ | $\begin{gathered} 3 \\ \text { Hour } \end{gathered}$ |
| 0-400 ft |  |  |  |  |  |  |  |  |  |  |
| All | 0 | 0 | 0 | 1 | 5 | 0 | 0 | 3 | 4 | 5 |
| Rear-End | 0 | 0 | 1 | 2 | 4 | 0 | 0 | 4 | 4 | 7 |
| 400-1320 ft |  |  |  |  |  |  |  |  |  |  |
| All | 0 | 0 | 0 | 5 | 5 | 0 | 2 | 5 | 5 | 6 |
| Rear-End | 0 | 1 | 1 | 4 | 6 | 0 | 2 | 4 | 5 | 6 |
| 0-1320 ft |  |  |  |  |  |  |  |  |  |  |
| All | 0 | 0 | 1 | 3 | 6 | 0 | 1 | 5 | 5 | 7 |
| Rear-End | 0 | 0 | 1 | 4 | 5 | 0 | 1 | 5 | 5 | 8 |

Note: Max value is 8 intersections

Table 6.5 shows the number of intersections to have a strong or very strong correlation between hard-acceleration and all collisions, specifically rear-end collisions, and specifically rightangle collisions. Right-angle collisions were added to the hard-acceleration analysis because it was speculated that vehicles rapidly accelerating to cross the intersection before the red signal would be in direct conflict with cross street traffic. For this same reason, an additional distance range, $-200-0 \mathrm{ft}$, was included in order to capture hard-acceleration events occurring after the stop bar. Like hard-braking, the 3-hour time bin was the most effective in correlating hardacceleration to crashes. Additionally, like hard-braking, in the southbound direction, in the 3-hour time bin, all 8 intersections had a strong or very strong correlation between rear-end collisions and hard-acceleration events occurring in the 0-1320 ft region. Interestingly, the distance range where right-angle collisions are most likely to occur, - $200-0 \mathrm{ft}$, had the least number of intersections with a strong or very strong correlation between right-angle collisions and hard-acceleration events.

Table 6.5. Number of intersections to have a strong or very strong correlation between hardacceleration events and collisions for different time bins

|  | NB |  |  |  |  | SB |  |  |  |  |

| 0-1320 ft |  |  |  |  |  |  |  |  |  |  |
| All Collisions | 0 | 0 | 1 | 3 | 5 | 0 | 1 | 4 | 4 | 7 |
| Rear - End | 0 | 0 | 0 | 4 | 3 | 0 | 1 | 4 | 4 | 8 |
| Right-Angle | 0 | 0 | 1 | 3 | 6 | 0 | 1 | 5 | 5 | 7 |

Note: Max value is 8 intersections
Due to there being 4 million more hard-acceleration events in Indiana than hard-braking events in July 2019, it was hypothesized that hard-acceleration would be a better predictor of crashes than hard-braking. However, in this study, this was not true. In the $0-1320 \mathrm{ft}$ region across all time bins for all collisions and rear-end collisions, hard-acceleration had 49 strong / very strong correlations, while hard-braking had 57. Likewise, in the 400 - 1320 ft region, hard-acceleration had 38 strong / very strong correlations, while hard-braking had 57. The only range where hardacceleration had more strong / very strong correlations was the $0-400 \mathrm{ft}$ region. In this region across all time bins for all collisions and rear-end collisions, hard-acceleration had 46 strong / very strong correlations while hard-braking had 40.

### 6.3 Volume Correlation

Finally, to understand the relationship between traffic volume and crashes, hard-braking, and hard-acceleration, a Spearman's rank order correlation test was performed. The volume data was collected from imbedded loop detectors for 3 weekdays in July 2019 and then averaged to
estimate intersection volume. Table 6.6 shows the results of this analysis for 4 different time bins. The correlation between volume and crashes increased as the time bins increased, while both hardbraking and hard-acceleration remained strongly to very strongly correlated with volume for all time bins. The strong correlation between hard-braking and hard-acceleration may not be surprising but suggests it can be a powerful tool for assessing intersections with potential safety issues without waiting for crash data. Intersections with a disproportionate amount of hard-braking / hard-acceleration events could be a strong indicator that the intersection needs to be evaluated further.

Table 6.6. Spearman's correlation between volume and crashes, hard-braking, and hardacceleration for multiple time bins

|  | 30 min | 1 Hour | 2 Hour | 3 Hour |
| :---: | :---: | :---: | :---: | :---: |
| Crashes | 0.38 | 0.48 | 0.56 | 0.63 |
| Hard-braking | 0.72 | 0.74 | 0.76 | 0.74 |
| Hard-acceleration | 0.79 | 0.82 | 0.83 | 0.83 |

## 7. DATA REPRESENTATIVENESS

### 7.1 The Big Question

Connected vehicle data is opening new frontiers for agencies to evaluate the performance of their road networks. In addition to hard-braking and hard-acceleration, the resulting data sets also have the capabilities of providing agencies with a rich set of data, such as traffic signal performance measures, interstate congestion, and common detours around road closures (Desai et al., 2020a; Hunter, Saldivar-Carranza, et al., 2021; McNamara et al., 2015; E. Saldivar-Carranza et al., 2020).

However, many agencies are concerned about the representativeness of the data. In fact, the lack of any systematic evaluation of regional variation in penetration is perhaps the biggest barrier to widespread use of connected vehicle data by transportation agencies. This chapter presents a methodology for calculating connected vehicle percent penetration using two data sets: Department of Transportation (DOT) collected traffic count data and connected vehicle (CV) trajectory data. This chapter reports the observed penetration of connected vehicles observed adjacent to selected count stations in the states of California (CA), Connecticut (CT), Georgia (GA), Indiana (IN), Minnesota (MN), North Carolina (NC), Ohio (OH), Pennsylvania (PA), Texas (TX), Utah (UT), and Wisconsin (WI).

The organization of this chapter begins by discussing the locations and data used in this study, and then, explains the methodology used to calculate the hourly, daily, and monthly percent penetration for each station. Next, section 6.4 Aggregate Results discusses the percent penetration Indiana and for all 11 states aggregated over all applicable stations. Finally, section 6.5 Disaggregate Results delves into individual stations. Four example outlier stations are explored in depth to provide further understanding behind how the percent penetrations are calculated and to understand potential reasons for the stations' outlying percent penetration.

### 7.2 Data

For this study, 381 continuous count stations were selected to be geographically distributed, represent both interstate and non-interstate roadways, have a variety of traffic volumes, and to be in both rural and urban environments (Figure 7.1).

Figure 7.1. Locations of DOT count stations used in this study

Table 7.1 provides information on the number of count stations divided by interstate, noninterstate, rural, and urban. Not every count station has data available for every hour, day, or month; therefore, Table 7.1 also differentiates between the number of count stations used in August 2020 and August 2021. While overall 381 count stations were used in this study, only 343 stations reported data in August 2020 and 349 stations reported in August 2021. There were 315 count stations that reported data both in August 2020 and August 2021.

Table 7.1. Count Station Attributes

| State | Interstate | Non-Interstate |  |  | Rural | Urban |  |  |  |  |

The traffic counts for the 381 count stations were obtained from their respective state DOTs and are, for the purposes of this study, considered the ground truth vehicle counts. Many different technologies are utilized at continuous count stations, such as inductive loops, piezoelectric sensors, and magnetic sensors (Federal Highway Administration, 2016). An example count station, located on I-70 in Indiana, utilizes inductive loops, as shown in Figure 7.2, and the location of inductive loop sensors is identified with callout i.

Figure 7.2. Inductive loops (i) at Indiana station 950106 (I-70 MM 25.8)

### 7.2.1 DOT Traffic Count Data

The majority of the traffic volume data (aggregated by hour) used in this study are publicly available online. However, some data was collected via correspondence with the DOT. The following list details how the DOT counts were collected. Additional details for each state's analysis are provided in Appendix A.

- CA: Performance Measurement System (Caltrans, n.d.)
- CT: Provided via email
- GA: Traffic Analysis and Data Application (GDOT \& Drakewell, n.d.)
- IN: Traffic Count Database System (INDOT \& MS2, n.d.)
- MN: Traffic Forecasting and Analysis Data Products (MnDOT, n.d.)
- NC: Traffic Data Management System (NCDOT \& MS2, n.d.)
- OH: Traffic Monitoring Management System (ODOT \& MS2, n.d.)
- PA: Traffic Information Repository (PennDOT, n.d.)
- TX: Traffic Count Database System (TXDOT \& MS2, n.d.)
- UT: Performance Measurement System (Iteris \& UDOT, n.d.)
- WI: Provided via email

### 7.2.2 Vehicle Trajectory Data

The vehicle trajectory data used in this chapter consists of anonymized individual waypoints that are collected every three seconds along with an anonymized trajectory identifier and GPS, timestamp, and heading information. This data was obtained through a third-party provider. This provider receives its data directly from the original equipment manufacturers (OEMs).

The vehicle trajectory counts were obtained by identifying quarter mile geofence regions near the count station that spanned the entire width of the road. In some cases, due to intersections, driveways, or curves in the road, the geofence region was shortened to avoid these features. The vehicle trajectory waypoints located inside the geofence region were selected, and the number of unique trajectories were counted. To account for trip chaining, if a trajectory identifier appeared more than 10 minutes apart or in the opposite direction, it was counted as an additional trip (Hunter, Mathew, Cox, et al., 2021; Hunter, Mathew, Li, et al., 2021).

### 7.3 Methodology

62 days across August 2020 and August 2021 were analyzed for 11 states (CA, CT, GA, IN, MN, NC, OH, PA, TX, UT, and WI). In addition, a longer longitudinal analysis for Indiana was conducted for the following months: July 2019, January 2020, June 2020, July 2020, September 2020, April 2021, May 2021, June 2021, July 2021, September 2021, October 2021, January 2022, and February 2022.

To calculate the hourly percent penetration, the DOT and vehicle trajectory counts were aggregated by hour. This was calculated by

$$
\begin{equation*}
H_{p}=\left(\frac{V_{h}}{C_{h}}\right) 100 \tag{Eq. 1}
\end{equation*}
$$

where $H_{p}$ is the hourly percent penetration, $\mathrm{V}_{\mathrm{h}}$ is the hourly count of unique vehicle trajectories, and $C_{h}$ is the hourly count of vehicles to pass the count station. The hourly INDOT counts, hourly vehicle trajectory counts, and resulting hourly percent penetration for an I-70 count station in Indiana for August 2, 2021 are shown in Figure 7.3.

Figure 7.3. Hourly counts and percent penetration for Indiana station 950106 (I-70 MM 25.8) on Monday August 2, 2021

The daily percent penetration was determined by

$$
\begin{equation*}
D_{p}=\left(\frac{\sum V_{h}}{\sum C_{h}}\right) 100 \tag{Eq. 2}
\end{equation*}
$$

Where $D_{p}$ is the daily percent penetration, $V_{h}$ is the hourly count of the vehicle trajectories, and $C_{h}$ is the hourly count of the vehicles to across the count station. Table 7.2 contains the daily counts and resulting daily penetration for an I-70 location in Indiana.

The monthly percent penetration is calculated using the daily counts from the entire month using

$$
\begin{equation*}
M_{p}=\left(\frac{\sum V_{d}}{\sum C_{d}}\right) 100 \tag{Eq. 3}
\end{equation*}
$$

where $\mathrm{M}_{\mathrm{p}}$ is the monthly percent penetration, $\mathrm{V}_{\mathrm{d}}$ is the daily count of vehicle trajectories, and $\mathrm{C}_{\mathrm{d}}$ is the daily count of the vehicles to cross the count station. Table 7.3 contains the number of INDOT counts and vehicle trajectory counts the 31 days in August 2021. The resulting monthly penetration is shown at the bottom. This methodology was replicated to determine statewide, monthly percent penetration. The statewide, monthly percent penetration is calculated using the monthly counts from the stations using

$$
\begin{equation*}
S_{p}=\left(\frac{\sum V_{m}}{\sum C_{m}}\right) 100 \tag{Eq. 4}
\end{equation*}
$$

where $S_{p}$ is the statewide, monthly percent penetration, $V_{m}$ is the monthly count of vehicle trajectories, and $\mathrm{C}_{\mathrm{m}}$ is the monthly count of the vehicles to cross the count station.

A weighted average approach of aggregating raw counts, instead of percentages, was chosen to eliminate the effects of outlier hourly or daily percent penetrations. Additionally, hours and stations with missing or incomplete DOT data were removed from the percent penetration calculations.

The percent penetration hourly trend was the very similar across all 11 states, an example for Indiana is shown in Figure 7.6. Typically, the percent penetration is the highest and is relatively constant during the daylight hours. Since the dataset used in this study contains only passenger vehicles, as the number of passenger vehicles dropped during the evening and nighttime hours and
the number of commercial vehicles decreased at a lesser rate, the percent penetration dropped to a low point between 1am and 3am before beginning to rebound as passenger vehicles reenter the road network.

Between August 2020 and August 2021, the overall percent penetration across all stations and states rose from $3.8 \%$ to $3.9 \%$. Of the 11 states, 9 states saw an increase in percent penetration. The average increase was $0.14 \%$. Minnesota and Texas were the two states that saw a decrease in percent penetration. Minnesota's decreased by $0.5 \%$ (attributable to a couple high percent penetration stations reporting in August 2020, but not August 2021), and Texas's decreased by $0.03 \%$. Of the 315 stations reporting data in both August 2020 and August 2021, 85\% saw an increase in percent penetration. The average percent increase was $0.7 \%$. Figures detailing the differences between August 2020 and August 2021 are presented in section 6.4 Aggregate Results and section 6.5 Disaggregate Results.

### 7.4 Aggregate Results

### 7.4.1 Indiana

A longitudinal analysis for fifteen months between July 2019 and February 2022 was completed, shown in Figure 7.4. In July 2019, the month used in the SR-37 hard-braking and hardacceleration crash analysis discussed in the earlier chapters, the percent penetration was under $2 \%$. The percent penetration then doubled by January 2020. This increase is likely due to an increase in the amount of data provided to the third-party data collector rather than a massive increase in connected vehicles purchased. COVID-19 pandemic restrictions began in March 2020, which led to a decrease in passenger vehicles on the road. While volume and percent penetration are independent of each other, a slight decrease in penetration occurred after the start of the COVID19 restrictions. The data used in this study is collected from passenger vehicles only. Since passenger vehicle traffic decreased at a faster rate and greater magnitude than truck traffic, the percent penetration dipped slightly (Goenaga et al., 2021). As the pandemic wore on, the percent penetration rose slightly and then hovered in the $4.5 \%-5 \%$ range.

Figure 7.4. Average monthly penetration over time by road type for Indiana

In addition to a multi-year analysis, day of week and time-of-day analyses were performed. Figure 7.5 shows the average percent penetration by day of week aggregated over August 2021 for all count stations in Indiana. Percent penetration is at its lowest during the middle of the work
week, Tuesday, Wednesday, and Thursday, and at its highest on Sundays. Interestingly, while the difference in percent penetration between non-interstates and interstates remains fairly constant between Tuesday and Thursday, the difference begins to shrink on Friday until it is negligible on Sunday. Perhaps, this could show the effect of commercial truckers taking time off for the weekend. Figure 7.6 shows the average percent penetration by time-of-day aggregated over August 2021 weekdays for all count stations in Indiana. Percent penetration is at its lowest during the early morning hours when the commercial truck volume is relatively high and passenger volume is relatively low. As passenger vehicles begin entering the roadways, the percent penetration jumps up to $4.5 \%-5 \%$, where it stays until about 7:00pm.

Figure 7.5. Average percent penetration by day of week for August 2021 aggregated over all stations in Indiana

Figure 7.6. Aggregated average percent penetration by time-of-day for August 2021 aggregated over all stations in Indiana

### 7.4.2 Additional States

Once Indiana's percent penetration had been analyzed, the study was broadened to include 10 other states with a focus on the months of August 2020 and August 2021. In total, roughly 15 million connected vehicle trajectory journeys in August 2020 and 19 million trajectory journeys in August 2021 were compared to 405 million DOT collected vehicle counts in August 2020 and 485 million vehicle counts in August 2021. The overall average percent penetration was $3.8 \%$ in August 2020 and $3.9 \%$ in August 2021. Figure 7.7 depicts the number of connected vehicle trajectory journeys and number of DOT collected vehicle counts minus the number of connected vehicle trajectory journeys. Additionally, Figure 7.7 shows the average percent penetration by day and for the whole month. The sawtooth pattern exhibited by the percent penetration can be explained by the trend shown in Figure 7.5. The percent penetration is at its lowest during the work week, but then sees an increase during the weekend.

Figure 7.8 drills down to the percent penetration for each of the 11 states for August 2020 and August 2021. For the majority of the states, percent penetration increased at least slightly between August 2020 and August 2021. The differences in the amount of change between August 2020 and August 2021 between the 11 states can possibly be attributed to the variation in number and types of stations reporting data over the two months (Table 7.1).

(a) August 2020

August 2021

Figure 7.7. Summary plots of all stations depicting number of connect vehicle trajectory journeys, number of DOT collected vehicle counts minus the number of connected vehicle trajectory journeys, and the average percent penetration by day and for the month

- Aug 2020 ■ Aug 2021

Figure 7.8. Percent penetration for 11 states for August 2020 and August 2021

Figure 7.9 presents similar information to Figure 7.8; however, the percent penetration is shown geographically. Penetration tends to be higher in the Midwest than in the more southern, coastal states. While the exact reasoning behind the differences in percent penetration is beyond the scope of this project, this thesis does offer some speculation. The data set used in this study doesn't include all vehicle makes. Perhaps, some states have a higher percentage of the vehicle makes included in the data than other states. Additionally, due to the lack of winter weather and subsequent salt and brine distribution, vehicles may be able to last longer in southern states leading to a larger number of older non-connected vehicles on the roadways.

Figure 7.9. Spatial distribution of percent penetration for 11 states

Figure 7.10 drills down even further and provides the percent penetration for August 2020 and August 2021 for all 11 states broken down by interstate, non-interstate, rural, and urban stations. Note each station was represented twice as each station is any combination of interstate / non-interstate and rural / urban. On average, the percent penetration varied by $0.6 \%$ between the 4 categories with the greatest difference being $1.1 \%$ for August 2020 and $1.2 \%$ for August 2021 and the smallest difference being 0.1\% for both August 2020 and August 2021.

$\square$ Interstate $\square$ Non-Interstate $\square$ Rural $\square$ Urban
(a) August 2020
(b) August 2021

Figure 7.10. Average percent penetration by state for interstate, non-interstates, rural, and urban stations

Finally, Table 7.4 presents a station summary table showing the lowest, median, and highest percent penetrations for each state in August 2021. For interstate stations, the lowest percent penetration was a California station with a percent penetration of $2.1 \%$. Meanwhile, for non-interstate stations, an Indiana station had the lowest percent penetration at $1.6 \%$. For both interstate and non-interstate categories, Wisconsin had the stations with the highest percent
penetration, $18 \%$ for an interstate station and $10 \%$ for a non-interstate station. The median values across all 11 states were $4.1 \%$ and $4.3 \%$ for interstate and non-interstates, respectively. The interquartile range for both types combined was between $3.3 \%$ and $5.0 \%$ with a mean of $4.2 \%$. As a reminder, Table 7.1 provides the sample size for the number of interstate and non-interstate stations. The number of interstates count stations evaluated ranged from 9 to 34 for CA / CT and IN, respectively. The number of non-interstates count stations evaluated ranged from 6 to 29 for CT and IN, respectively.

Table 7.4. Station summary table for interstate and non-interstate percent penetrations for 11 states in August 2021

|  | Minimum |  | Median |  | Maximum |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Interstate | Non-Interstate | Interstate | Non-Interstate | Interstate | Non-Interstate |
| CA | $2.1 \%$ | $2.3 \%$ | $2.7 \%$ | $3.3 \%$ | $2.9 \%$ | $5.5 \%$ |
| CT | $2.3 \%$ | $2.5 \%$ | $3.0 \%$ | $3.2 \%$ | $4.3 \%$ | $3.4 \%$ |
| GA | $3.1 \%$ | $2.4 \%$ | $3.9 \%$ | $3.7 \%$ | $4.6 \%$ | $6.7 \%$ |
| IN | $3.4 \%$ | $1.6 \%$ | $4.4 \%$ | $4.6 \%$ | $6.2 \%$ | $6.7 \%$ |
| MN | $2.1 \%$ | $3.5 \%$ | $5.0 \%$ | $5.9 \%$ | $6.1 \%$ | $9.0 \%$ |
| NC | $3.1 \%$ | $3.0 \%$ | $3.5 \%$ | $4.2 \%$ | $4.8 \%$ | $4.8 \%$ |
| OH | $3.8 \%$ | $3.6 \%$ | $4.8 \%$ | $4.1 \%$ | $6.0 \%$ | $7.5 \%$ |
| PA | $2.9 \%$ | $2.8 \%$ | $3.7 \%$ | $3.8 \%$ | $5.2 \%$ | $5.0 \%$ |
| TX | $2.6 \%$ | $3.2 \%$ | $4.5 \%$ | $5.5 \%$ | $6.4 \%$ | $7.0 \%$ |
| UT | $2.3 \%$ | $2.2 \%$ | $2.7 \%$ | $2.7 \%$ | $3.5 \%$ | $4.5 \%$ |
| WI | $4.3 \%$ | $4.5 \%$ | $5.2 \%$ | $6.0 \%$ | $18.0 \%$ | $10.0 \%$ |
| AII | $2.1 \%$ | $1.6 \%$ | $4.1 \%$ | $4.3 \%$ | $18.0 \%$ | $10.0 \%$ |

### 7.5 Disaggregate Results

Once the aggregate results were analyzed for each of the 11 states, the individual stations were analyzed. Figure 7.11 shows the percent penetration by station for August 2020 and August 2021. The percent penetration at individual stations ranged from $1.6 \%$ to $16.3 \%$ in August 2020 and $1.6 \%$ to $18.0 \%$ in August 2021. Figure 7.12, Figure 7.13, and Figure 7.14 present box plots of the percent penetration by station by hour, by station by day, and by station. $99 \%$ of the August 2020 and August 2021 hours analyzed had percent penetrations of $11 \%$ or less $(472,000$ out of 479,000 hours). $98 \%$ of the August 2020 and August 2021 days analyzed had percent penetrations between $2 \%$ and $8 \%$ ( 19,800 out of 20,100 days). The following sections will examine some
outliers from California, Minnesota, Texas, and Wisconsin. Appendix B contains additional examples of specific stations for all 11 states.

Figure 7.12. Box plot: Percent penetration by station by hour

Figure 7.13. Box plot: Percent penetration by station by day

Figure 7.14. Box plot: Percent penetration by station

### 7.5.1 CA: CA-25

CA-25 is identified as CA 1 in Figure 7.11 and Figure 7.15. Unlike the majority of the other states analyzed in this study, Caltrans treats each direction, ramp, and high occupancy lane as a unique station. Therefore, in order to determine the full roadway volume, the appropriate Caltrans stations were summed together and treated as one station id. Additionally, not every hour was $100 \%$ observed. Hours with less than a $100 \%$ observation rate were excluded along with the corresponding connected vehicle trajectory counts for that same hour. CA- 25 consists of two Caltrans stations: 501019111 and 501019112.

CA-25 was chosen for further analysis as the percent penetration was $5.5 \%$ in August 2020, but $3.9 \%$ in August 2021. Figure 7.15 shows the location of CA-25. Figure 7.16 depicts the percent penetration calculations for Monday August 3, 2020 and Tuesday August 3, 2021. Adjacent to the calculations are maps with the connected vehicle trajectory points plotted. Table 7.5 displays the hourly percent penetration for both August 3rds. The reason for this large decrease in percent penetration can be explained by the DOT traffic counts seeing a $46 \%$ increase while the connected vehicle journey counts only saw a 6\% increase. The underlying cause for this discrepancy in percent increase is currently unknown, but it does highlight the value of aggregating over numerous sites so that such anomalies can be accounted for without overly skewing the data.

Figure 7.17 shows screen captures of PeMS for Caltrans stations 501019111 and 501019112 for hourly counts on August 3, 2020 and August 3, 2021 (Caltrans, n.d.).

Figure 7.17. Screen shots of California's CA-25 station traffic counts from Caltrans's PeMS (Caltrans, n.d.)

### 7.5.2 MN: 48

The next station to be analyzed is station 48 in Minnesota, identified as MN 1 in Figure 7.12. This station was chosen as an example site to explain the large variation in hourly percent penetrations show in Figure 7.12. Figure 7.18 shows the location of MN 1, and Figure 7.19 depicts the percent penetration calculations for 2am on August 21, 2021 along with a map of the associated trajectory points. As shown, the $100 \%$ percent penetration can be attributed to only one vehicle, a vehicle that reports to the connected vehicle dataset used in this study, passing the count station. Table 7.6 presents the hourly percent penetration for the entire day of August 21, 2021. While the daily percent penetration of station 48 on August 21, 2021 is $6.3 \%$, percent penetration fluctuates between $0 \%$ and $100 \%$ over the course of the day. This station highlights the importance of aggregating over many hours, instead of relying on just one hour for calculating the percent penetration, especially for low volume stations.

The Minnesota traffic count information was downloaded for MnDOT's Data Product webpage (MnDOT, n.d.). Table 7.7 shows the hourly data collected from MnDOT for station 48 for August 21, 2021. The counts received were differentiated by direction; therefore, the directional counts were summed to represent the traffic counts for the entire roadway.

### 7.5.3 MN: 1335

For the by station box plot (Figure 7.14), Minnesota station 1335, MN 2, was analyzed. This station is an example of an outlier station with a large percent penetration. Figure 7.20 shows the location of station 1335, and Figure 7.21 depicts the percent penetration calculations for August 9, 2020. Table 7.8 shows the hourly percent penetration for station 1335 on August 9, 2020.

Throughout the day of August 9, 2020, the percent penetration ranges from $2 \%$ at 2 am to $41 \%$ at 9am. This station's August 2020 percent penetration of $11.6 \%$ is just over double the August 2020 percent penetration for the state of Minnesota. This points to the importance of monitoring many locations and not assuming that the statewide percent penetration is applicable to all locations.

Table 7.9 shows the hourly data collected from MnDOT for station 48 for August 21, 2021.

Figure 7.20. Location of Minnesota station 1335

### 7.5.4 WI: 400026

The last station analyzed in the main body of this thesis is Wisconsin station 400026, shown as WI 1 in Figure 7.13 and Figure 7.14. Like Minnesota station 1335, this station is an example of an outlier station with many days of high percent penetration. Figure 7.22 shows the location of station 400026, and Figure 7.23 depicts the percent penetration calculations for August 8, 2021 along with a visual of the vehicle trajectory points. Table 7.10 shows the hourly percent penetration for August 8, 2021 for station 400026. The hourly percent penetration ranged from $15 \%$ at 8 am to
$52 \%$ at 4am. The August 8, 2021 daily percent penetration was $22 \%$, and the August 2021 monthly percent penetration was $18 \%$. This is over 3 times the percent penetration of Wisconsin for August 2021. As with the Minnesota station 1335, the reasoning for the very large percent penetration is unknown. The aggregation of percent penetration over numerous stations helps smooth out these outliers.

The Wisconsin count data was obtained directly from a WisDOT employee via email. Table 7.11 is an example of some of the provided data for station 400026 on August 8, 2021. Like Minnesota, the counts were provided for each direction; therefore, the directional, hourly counts were aggregated before they were compared to the number of connected vehicle journeys.

Figure 7.22. Location of Wisconsin station 400026

### 7.6 Conclusion

The aim of this chapter is to address a common concern of agencies, data representativeness. This chapter details a study that looked at 381 stations across 11 states for two months, August 2020 and August 2021, with an extended fifteen-month analysis for Indiana. Section 6.2 Data describes the station locations, DOT data sources, and the vehicle trajectory data. Section 6.3 Methodology explains the calculation process for determining the hourly, daily, and monthly percent penetration. Sections 6.4, Aggregate Results, and 6.5, Disaggregate Results, provide the resulting percent penetrations. Section 6.4 Aggregate Results focuses on the average percent penetration for entire states over one month, while section 6.5 Disaggregate Results drills down to the percent penetration for individual stations at the hourly, daily, and monthly levels. Additionally, Section 6.5 Disaggregate Results highlights the need to aggregate across hours, days, and even
stations in order to smooth out outliers and obtain a reasonable average percent penetration for that particular station or state. Likewise, just as one station's percent penetration doesn't always reflect the state's average, a state's average percent penetration shouldn't be assumed to be the same for all locations across the state.

## 8. CONCLUSION

This thesis presents a methodology for evaluating intersections for safety improvements utilizing one month of hard-braking data and/or one month of hard-acceleration data. This study compares crash data over a period of 4.5 years (January 2016 to July 2019) at 8 signalized intersections with one month of hard-braking data (July 2019) and one month of hard-acceleration data (July 2019) to determine if there was a statistical relationship between crashes and hardbraking / hard-acceleration events. Graphical illustrations comparing aggregated hard-braking events and crashes (Figure 4.2, Figure 5.3, Figure 5.4, Figure 5.8, and Figure 5.9) demonstrate a visual relationship between the crash and hard-braking / hard-acceleration data sets. A Spearman Rank Order Correlation test was used to evaluate the correlation between crashes and events for several distance ranges, time bins, and crash categories. The statistical tests show that there are strong and very strong correlations between crashes and hard-braking / hard-acceleration events (Table 6.2, Table 6.3, Table 6.4, and Table 6.5). Using a 3-hour time bins, a distance range of 01320 ft , and a focus on rear-end collisions, all 8 intersections in the southbound direction had a strong or very strong correlation between hard-braking / hard-acceleration and crashes.

Chapter 7 presents a methodology for assessing the penetration of connected vehicles on roadways. The percent penetration was assessed utilizing DOT and trajectory data from 381 location across 11 states in August 2020 and August 2021. In total, over 1 million hours, 1.7 billion count station records, and 70 million connected vehicle records were analyzed. Figure 7.8 and Figure 7.9 present the percent penetration for each of the states. Penetration ranges from a low of $1.6 \%$ in IN at station 990508 to a high of $18 \%$ in WI at station 400026 in August 2021.

A longitudinal analysis was performed over fifteen months between July 2019 and February 2022 for Indiana. Figure 7.4 shows the percent penetration for those fifteen months for interstate and non-interstate roads varied from a low of $1.8 \%$ in July 2019 to a high of $5.2 \%$ in January 2022.

A time of day analysis was performed using August 2021 Indiana data which shows that percent penetration ranged from $2.1 \%$ at $1: 00$ am to $5.3 \%$ at 7:00am and remained around $4.5 \%$ during the daylight hours (Figure 7.6). The boxpolots, Figure 7.12, Figure 7.13, and Figure 7.14, show the distribution of percent penetrations for hourly, daily, and by station. Finally, several example outlier stations are discussed.

Both the hard-braking and penetrations methodologies presented in this thesis are extremely scalable. Agencies could collect event data, such as hard-braking and hard-acceleration, for a large number of intersections and corridors, and then implement this method to assess all traffic signals within an urban area or an entire state for potential safety issues. Such analysis would be a relatively modest effort, and perhaps more importantly, require no investment in traffic signal infrastructure to collect this performance measure data (Hunter, Saldivar-Carranza, et al., 2021). Additionally, all states have highway performance monitoring systems allowing them to monitor the growth of connected vehicle penetration in their jurisdictions over time. Utilizing this information, agencies should be able to access the value of the connect vehicle data and the aggregation needed to obtain statistically robust performance measures (Hunter, Mathew, Li, et al., 2021).

## APPENDIX A: PERCENT PENETRATION DATA REPOSITORY

The purpose of appendix A is to provide additional access to the connected vehicle data and results. Links for a map of the count stations, a file of count station attributes, a folder with DOT count data used, data sources, and the hourly percent penetration calculations are shared. Additionally, data attributes are defined.

## Attribute Descriptions:

StationID: The ID used by the state to identify the location.

- Utah and California are two exceptions to this rule. Since multiple stationID's correspond to the same roadway location, the stations are identified as UT_\# and CA-\#. The UT Corresponding Stations and CA Corresponding Stations tabs detail which stations are used for each location.
- Ohio and Minnesota both have a stationID 103. They are differentiated by 103_OH and 103_MN.
ActualLat / ActualLong: The latitude and longitude of the station.
- Due to Utah and California having multiple stations per location, no latitude / longitude is included.
$\mathrm{I} / \mathrm{N}$ : Identifies station as either located on an interstate or non-interstate.
R/U: Identifies station as either located in a rural or urban setting. If this data was not provided by the state, a judgement was made using satellite imagery.

GeofenceMarker 1/2: Latitude and longitude of the boundaries of the geofenced region used to identify the applicable connected vehicle trajectory points.
RoadWidth: Width of the roadway. Used to provide the width of the geofence region.
Heading 1/2: The headings of both travel directions. Used to filter out vehicles traveling in the wrong direction (ie. Vehicles traveling over bridges or through underpasses).

State: The state the station is located in.

## Attributes:

Station: The ID used by the state to identify the location.

- Utah and California are two exceptions to this rule. Since multiple stationID's correspond to the same roadway location, the stations are identified as UT_\# and CA-\#. The UT Corresponding Stations and CA Corresponding Stations tabs detail which stations are used for each location.
- Ohio and Minnesota both have a stationID 103. They are differentiated by 103_OH and 103_MN.
Date: Day counts occurred
Hour: Hour counts occurred
DOT Count: Number of vehicles reported by the DOT's count station
CV Count: Number of unique connected vehicle journeys

## Percent: Percent penetration

$\%$ Penetration $=\frac{\sum \text { Unique } \text { Trajectories }}{\text { Dot Volume }}$

State: State station is located in.
I/N: Identifies station as either located on an interstate or non-interstate.
$\underline{\mathrm{R} / \mathrm{U}}$ : Identifies station as either located in a rural or urban setting.

## APPENDIX B: EXAMPLE STATIONS FOR EACH STATE

Appendix B provides an example station for each state. States are listed in alphabetical order.

## California:

Station Name: CA-19 (corresponding Caltrans stations: 1126458, 1126455, 1126470, 1126472) Latitude: 32.836097
Longitude: -116.962089
